## 1.1 Motivation

The isolation of graphene in 2004 has led to a growing interest of the scientific community in two-dimensional (2D) materials revealing extraordinary properties. It might seem surprising that 2D systems were not considered as a real possibility before since they are often idealized in thought experiments, for example when investigating toy models of more complex higher dimensional systems. In fact, their very existence was not expected *a priori* because at first sight they seem to violate the Mermin-Wagner-Hohenberg theorem [1–3], a no-go theorem that forbids ordering below three dimensions at finite temperature<sup>1</sup>. Graphene paved the way for the search for similarly stable 2D materials, and since it was isolated, a plethora of these has been discovered. A vast set of open problems remains to be solved within the realm of the fascinating and counterintuitive properties of the now huge variety of existing 2D systems. In particular, in some of these, the effect of electron interactions is non negligible, leading to emergent phenomena. These are collective effects that emerge as a result of the interactions between the individual components of a system. The properties of the system's components do not directly percolate up; instead, they shape the interactions that dictate the system's properties sometimes in rather unexpected ways, leading to counter intuitive behavior.

Interacting electron systems are often tackled by carrying out computer simulations. Quantum Monte Carlo (QMC) is a family of numerical methods that are amply applicable to condensed matter physics problems, and that are particularly well suited to study strongly correlated electrons. Despite the system size being constrained due to limited simulation time, reliable and accurate solutions are provided to the otherwise intractable quantum many-body problem. The class of QMC algorithms that is used in this work was introduced in the 1980's in a series of seminal papers by Hirsch, Blankenbecler, Scalapino and Sugar [4–10], but it saw a recent surge [11–23] due to the increase in computational power, and algorithmic development. As a result, the field is currently very active and method optimization can prove crucial in applications to widely studied physical models of electron interactions. In particular, the recent computational and algorithmic developments allow the study of both larger and lower temperature systems.

In this work, determinant QMC is used to simulate a Transition Metal Dichalcogenide (TMD) nanoribbon, a nanostructure made of this recent member of the 2D materials family.

## 1.2 Strongly correlated electron systems

Condensed matter physics is concerned with the emergence of the properties of quantum materials from complexity. The central concept within this approach is that of symmetry breaking. When a phase transition occurs, a system is said to condense into a phase of lower symmetry. A simple pictorial example is the transition from a gas to a solid. Statistically, any point within a gas is equivalent, that

---

<sup>1</sup>2D materials are stable because not all the conditions of Mermin-Wagner-Hohenberg theorem are verified, namely the condition of short-ranged interactions. The issue is quite subtle, and is beyond the scope of this work.

is, on average, the surroundings of all points look similar. Formally, the system is then said to be fully translationally invariant. On the other hand, in a solid, a point is only equivalent to a discrete set of other points. In fact, a simplified view of a solid consists of a periodic arrangement of atoms occupying the points of a lattice. Any point on the lattice can be reached starting from any other point upon translation by a lattice vector. Thus, a system that makes a transition from the gaseous to the solid state becomes invariant only under a discrete set of translations, rather than a continuous one.

A framework that is commonly used to identify symmetry breaking is the Landau Ginzburg (LG) theory of phase transitions. The theory gives a prescription to discover phase transitions. More precisely, it gives criteria for a symmetry to become manifest. Although this framework is very useful, it turns out that the search for order relies on symmetry ideas well beyond condensed matter. Symmetry breaking gives rise to emergent phenomena. The idea of emergence rests on a constructionist, rather than a reductionist hypothesis: that the behavior of the many does not trivially follow from the behavior of the few. As P.W. Anderson puts it, “The ability to reduce everything to simple fundamental laws does not imply the ability to start from those laws and reconstruct the universe.” [24]

The broad scope of condensed matter comes from the sheer number of possibilities that the symmetry breaking approach affords. For the specific case of the LG theory, one can study the emergence of magnetism, superconductivity, or superfluidity, just to name a few. However, as we shall see, sometimes the LG theory fails to capture a system’s behavior, and we must resort to other theories to identify these, or other eventual properties that might arise. The Landau Ginzburg procedure can be summarized as follows: identify an order parameter reflecting the underlying symmetry of the system, and minimize the free energy in order to deduce conditions for the symmetry to become manifest, leading to a phase transition. The drawback of this approach is that it might be difficult to identify an order parameter in the first place. Moreover, even if we do manage to find one, the usual procedure may be impossible to perform. It can easily happen that the degree of complexity of the order parameter is simply too high. Additionally, and perhaps more importantly, not all phase transitions can be described by the LG paradigm.

On the one hand, there are systems where a different kind of order arises. A prominent example is that of fractional quantum Hall effect, where (rather surprisingly!) the *quasi-particles* describing the excitations of the quantum Hall fluid carry *fractions* of the electron charge. There is an intimate connection between charge fractionalization and topology, which may be understood in terms of the properties of the Laughlin states describing the quantum Hall fluid. However, while it is tempting to try to characterize the latter in terms of the LG paradigm, it must actually be regarded as a distinct type of matter, where “topological order” arises [25].

On the other hand, for the so called strongly correlated systems we shall focus on in this work, there are phenomena which emerge specifically due to the interacting nature of the problem. They are elusive because a description in terms of the LG paradigm does not yield a behavior consistent with what is observed empirically. Instead, order emerges from the complexity created by the interactions among all the constituents. The LG theory fails because it ignores these interactions by disregarding fluctuations in the microscopic configuration of the system. This approximation consists of reducing

the complex interactions to an effective *mean field*, which is normally determined self consistently. Strongly correlated systems require an approach beyond mean field, which makes them both extremely interesting and notoriously difficult to tackle. The mean field view fails to describe them because it considers each constituent to interact only with an external entity representing the interactions with all other constituents, ignoring collective behavior. In fact, the failure of mean field theory is not limited to correlated systems, and its success in describing a given system depends, for example, on the dimensionality<sup>2</sup> and on the range of the particular type of interaction that is considered.

In many cases, mean field theory is too extreme an approximation. Nonetheless, its occasional failure at capturing the whole of a system's properties does not deem it useless. Actually, it is quite the contrary. Mean field is often used as a first approach to build an intuitive physical picture for the general properties and behavior of the system. Of course, this is done while keeping in mind that the description it provides is intrinsically insufficient. Clearly, to extract the features of a correlated system we must extend it to the fully interacting case.

Strongly correlated quantum matter is ubiquitous and is at the heart of today's most advanced electronic materials, namely organic conductors, high  $T_c$  (cuprate) superconductors, colossal magnetoresistance materials, and "heavy-fermion"<sup>3</sup> compounds. Actually, the problem of strong correlations has now expanded beyond condensed matter physics. Quark-gluon plasmas, believed to have been formed just a few microseconds after the Big Bang, also belong to this class of systems. Another example comes from atomic physics: ultracold atoms in optical lattices behave in a very similar way to correlated electrons. In fact, the behavior is so similar that these systems are being used as *de facto* quantum simulators of correlated electron systems [26].

A central piece in the understanding of correlated matter is the Hubbard model. It was introduced to bridge a gap between metals and magnetic insulators, building on the earlier work of Mott. The model is extremely simple. Electrons hop from atom to atom on a lattice, paying an energy penalty when they occupy the same site. This repulsive effect results in correlations beyond those that are always present due to the fermionic nature of the particles obeying the Pauli exclusion principle. In the limit of weak repulsion, the electrons are nearly free, and the system behaves like a metal. Otherwise, the electrons become localized at fixed atomic positions resulting in magnetic insulating behavior. The model is simple to formulate, but already includes correlation effects between all electrons in the solid. Thus, it is not surprising that an exact solution exists only in 1D [27], and higher dimensional versions are still being studied more than 50 years after the model appeared [28].

### 1.3 State of The Art

Solving the many-body problem remains one of the greatest challenges in physics. Following the wealth of attempts at such pursuit, certain phenomena arising due to the strong interactions in quantum systems are explained in different theoretical frameworks, namely superconductivity, the Mott

---

<sup>2</sup>Normally, there is an upper critical dimension  $d_c$  above which mean field is exact. Below  $d_c$ , its predictions might be useful qualitatively, but not quantitatively.

<sup>3</sup>The quasi-particles describing excitations in these materials behave like much heavier electrons, hence the name.

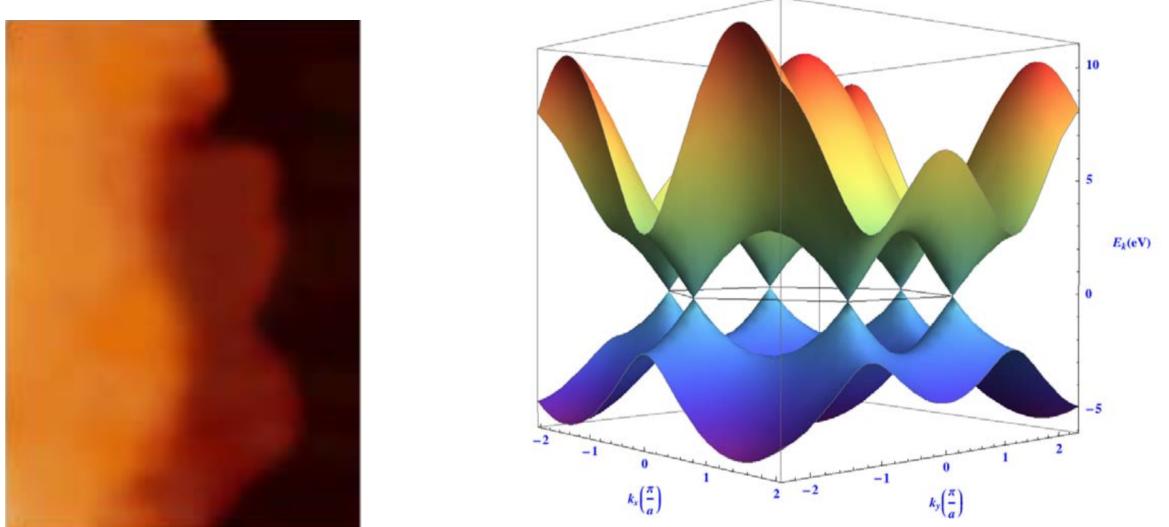

metal-insulator transition, and fractional quantum Hall effect. All of these breakthroughs represented revolutions in their respective fields with significant scientific and technological impact.

Only in very limited cases does an actual analytical solution exist for the Schrödinger equation for a system of interacting particles. One must resort to sophisticated approximation methods to obtain information about the role played by the competing interactions under various conditions in the aforementioned cases. It is then natural that numerical methods have become prominent as a tool for extracting useful information about this type of systems. QMC is amongst the most accurate and extensively studied ones.

The idea of all QMC methods is to reduce the interacting problem to solving a set of integrals, which can be evaluated numerically through a standard stochastic procedure. These integrals are arrived at upon formulating the quantum many-body description of the system using the Schrödinger equation. Hence the name Quantum Monte Carlo, which is used to distinguish it from Classical Monte Carlo. In the classical version, one measures thermal averages, while in the quantum version, one measures expectations of operators over the Hilbert space of the system, corresponding to physical observables that fluctuate with a dynamics given by the Schrödinger equation.

### 1.3.1 Beyond graphene: TMD nanoribbons

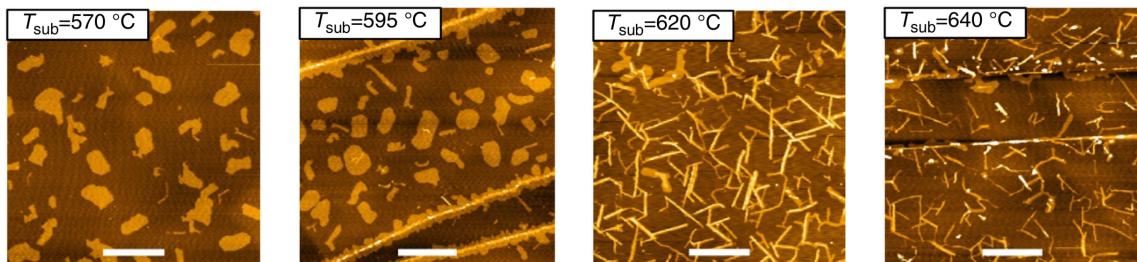

2D materials have steadily been attracting more and more attention since graphene was experimentally isolated from a graphite sample by mechanical exfoliation, yielding a system constituted by a single layer of atoms (Figure 1.1, left). Since then, numerous studies have been made due to the promising properties of these materials, and the interesting as-yet-unseen phenomena occurring within them, for example: unconventional quantum Hall effect, absence of localization, and electrons behaving like massless relativistic particles (Figure 1.1, right), providing a bridge between condensed matter physics and quantum electrodynamics [29].

**Figure 1.1:** Left: Atomic Force Microscopy (AFM) picture of a graphene monolayer. The black area is a substrate used for fabrication purposes. The dark orange area is a monolayer of graphene. Right: Dispersion relation of graphene. The black line represents the Fermi energy. Close to it, the dispersion relation is linear, corresponding to massless excitations (taken from [30]).

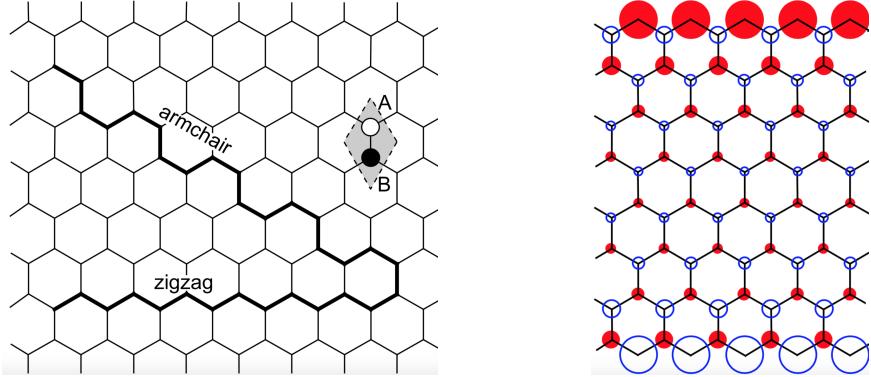

On the other hand, TMDs are a recent member of the 2D materials family [31–33]. TMDs have been attracting interest because they seem to overcome some of the drawbacks of graphene in technological applications. For example, monolayer graphene is gapless, while its bilayer counterpart has only a tunable, but small gap of the order of a tenth of an eV. Contrastingly, TMDs have an intrinsic gap in excess of 1 eV, being more promising in designing, for example, transistors. Hole-doped TMDs are expected to show topological superconductivity [34], while the superconducting phase of graphene has been predicted, but is not easily attained. Superconductivity in graphene-like 2D materials is important because it could boost high speed nanoelectronics. Moreover, the presence of transition metal atoms in TMDs suggests the possibility of magnetic ordering [35], which could be very relevant in nanospintronics applications. Both topological superconductivity and magnetic ordering arise due to the effect of strong electron correlations. Thus, to investigate these properties of TMDs when performing simulations, we need a computational method that is robust enough to capture the effects of electron interactions.

A nanoribbon consists of a 2D layer that can be regarded as infinitely long on one direction, but not on the other (Figure 1.2), so that edge states become relevant, and can be controlled to yield interesting properties. For simulation purposes, it is natural to assume translational invariance along the ribbon’s longitudinal direction, and use periodic boundary conditions (PBCs). On the other direction, we use open boundary conditions (OBCs), effectively considering zigzag edges (Figure 1.3, left).

**Figure 1.2:** Fabrication of TMD nanoribbons. From left to right, we see AFM images showing the appearance of nanostructures ranging from 2D nanoislands to nanoribbons, as the temperature of the substrate is increased. The nanoribbons are grown by taking advantage of the temperature dependence of shape transformations occurring during the nonequilibrium growth of this kind of surface-based nanostructures. (taken from [36])

A high density of low-energy electronic states is localized at the zigzag edges, decaying quickly in the bulk, which suggests the possibility of magnetic ordering. In fact, a mean field solution of the Hubbard model shows that magnetic moments are localized at the edges [37] (Figure 1.3, right). QMC has been used to investigate edge-state magnetism beyond mean field in graphene [38–42]. However, edge magnetism in TMD nanoribbons remains unexplored [43].

**Figure 1.3:** Left: Two possible terminations of a TMD nanoribbon condensing in a honeycomb lattice. Right: Local magnetic moments exist on the zig zag edges. The area of the circles corresponds to the magnitude of the magnetic moment, while the color red corresponds to a spin up density, and blue to a spin down density. The accumulation of  $e^-$  edge states leads to an AF ground state (opposite edges with opposite magnetic moment). (taken from [37])

While the zigzag graphene nanoribbon antiferromagnetic ground state is semiconducting, a state with interedge ferromagnetic orientation is a metal. An example of an application based on the switching between the two states is a magnetoresistive sensor. This device allows switching between low and high-resistance configurations, corresponding, respectively, to parallel, and antiparallel configurations of ferromagnetic leads at the ends of a nanoribbon. An important application of this project is precisely the investigation of the possibility of edge-state magnetism, as is observed in graphene nanoribbons, for TMD nanoribbons, which could yield similarly innovative applications.

### 1.3.2 Introduction to Quantum Monte Carlo

In principle, the properties of a quantum many-fermion system can all be deduced by solving an extremely complicated Schrödinger equation that takes into account the coupling of all (identical) particles of the system. However, for the majority of systems the resulting integrals have no analytic solution, so we solve the problem by numerical integration. But there is a myriad of methods to evaluate integrals numerically. How do we pick the best one for this case? It depends on the problem at hand, of course. Variational and Diffusion QMC are the simplest QMC methods that allow one to capture some properties of correlated systems. Although they already contain the main concepts used in this type of simulations, it is not always possible to use them. We will discuss their flaws and show how further refinement leads to the auxiliary field QMC method.

A variety of Quantum Monte Carlo (QMC) methods exists, using a sampling scheme based on the Metropolis algorithm, and variations thereof. However, applying them to many-fermion systems implies overcoming a significant obstacle common to all of them - the so called *fermion-sign problem*. Pauli's exclusion principle implies that the many-fermion wave function is antisymmetric, which leads to a sign oscillation that greatly impedes the accurate evaluation of averages. Thus, a straightforward weight interpretation of the wave function is not possible. In the case of the finite temperature algorithm, the cancellations that occur when computing the average of any physical observable lead to poor statistical properties of the estimators. This means that a massive amount of measurements requiring enormous

computer time are needed to obtain meaningful results. In the case of the zero temperature algorithms, the situation is even worse. It might not even be possible to design a stochastic process carrying the system to its ground state, as normally is done in “projective” methods<sup>4</sup>: the wave function that is used as an initial proposal turns out to converge to a bosonic one, and the fermionic character of the system is lost.

As was proven by Troyer, the *fermion-sign problem* has NP<sup>5</sup> computational complexity [44]. One of the greatest open questions in computer science is whether  $P = NP$ . Solving the *fermion-sign problem* would imply finding a solution to this problem, which would constitute a major breakthrough.

### 1.3.3 Monte Carlo Method in Classical Statistical Physics

Monte Carlo methods form the largest and arguably most important class of numerical methods used to approach statistical physics problems. In these notes we explain what Monte Carlo techniques are and why they are useful. Statistical physics often deals with computing quantities that describe the behavior of condensed matter systems. The main difficulty one faces when doing so has to do with the collective nature of these systems. Many identical components comprise these systems, and while the equations that govern the behavior of the whole may be easy to write down, their solution is in general a remarkably laborious mathematical problem. The exponentially large number of configurations of a typical condensed matter system can be daunting. Analytical solutions are more often than not hopeless and even numerical solutions are seemingly challenging. However, they give valuable information lying between theory and experiment, and connecting them.

Suppose you try to sample uniformly from the probability distribution of all possible configurations of one of the aforementioned systems. Changes are your algorithm will not end before the Universe does. This is the computational complexity hurdle. A related issue is that of finite size effects. We are far from being able to simulate a macroscopically sized system. At best we can simulate a system that has only a minuscule fraction of the actual size of the corresponding real world system. Amazingly there are techniques that allow us to efficiently extract elusive information out of relatively small size simulations. Nonetheless, increasing the system size consistently improves the reliability of a simulation. Thus, the more efficient the algorithm is, the larger the system we can simulate in a fixed time.

The sheer number of equations describing a condensed matter system, and sometimes the strong coupling between them deems the task of finding an exact solution either very tough or even impossible. It is not even clear whether an analytical solution would be of any use in many cases, and a statistical and numerical treatment often allows us to study more effectively the key properties of a system. Analytical solutions are rare. Exact solutions are an even rarer accomplishment. Not only do analytical solutions rely on approximations, but also numerical methods.

On the other hand, let us emphasize the striking victory of statistical mechanics. We are able to

---

<sup>4</sup>Methods that project a trial wave function onto the ground state.

<sup>5</sup>NP or nondeterministic polynomial time roughly meaning that one can devise an algorithm that verifies the "yes" answer to a decision problem in polynomial time in the system size. Note that the class  $P$  - of polynomial time algorithms - is a subclass of NP.

describe a system that is governed by a macroscopically large number of equations in terms of only a few variables. The loss of information in doing so is only apparent. The statistical description is so effective because most of the possible states of the system are extremely improbable when compared to the relevant very narrow part of configuration space. The success of the field is largely attributed to the averaging out that naturally occurs when we measured a property of a macroscopic system.

How do we set up a simulation of a physical system? We assume basic knowledge of statistical physics and focus only on the concepts that are essential for simulation purposes.

A system in state  $\mu$  makes transitions to state  $\nu$  at a rate  $R(\mu \rightarrow \nu)$

The Monte Carlo method is ubiquitous. Its central idea is to use randomness to produce accurate estimates of deterministic integrals. The term was coined by Nicolas Metropolis in 1949, first appearing in a seminal paper, in which it was described as a “statistical approach to the study of differential equations, or more generally, of integro-differential equations that occur in various branches of sciences”[Metropolis1949]. Although it was used as early as 1777 in an experiment known as Buffon’s needle - where one obtains an estimate of the constant  $\pi$  by repeatedly throwing a needle randomly onto a sheet of paper with evenly spaced lines - it was crucially developed in the Los Alamos National Laboratory during World War II where the development of the first atomic bomb was completed, the primary objective of the Manhattan Project. The method is particularly useful when one wants to sample from a probability distribution in an exponentially large state space. In fact, it can in principle be used to solve any problem allowing a probabilistic formulation.

The law of large numbers affords an approximation to integrals which can be written as an expectation of a random variable. Upon drawing enough independent samples from the corresponding distribution, the sample mean gets arbitrarily close to the integral at stake.

$$\mathbb{E}[f(X)] = \int dx f(x)p(x), \quad (1.1)$$

where  $p(x)$  is the distribution of  $X$ .

We could simply draw  $M$  independent and identically distributed samples  $x_{1,\dots,M}$  from  $p(x)$  and approximate the integral as

$$\frac{1}{M} \sum_{k=1}^M f(x_k), \quad (1.2)$$

which in most cases converges to the desired expectation, as long as  $M$  is large enough. How large?

$$\text{Var}\left(\frac{1}{M} \sum_{k=1}^M f(x_k)\right) = \frac{1}{M} \text{Var}(f(x_1)) \sim \mathcal{O}\left(\frac{1}{M}\right) \quad (1.3)$$

Thus, the correction to the sample mean is of order  $\mathcal{O}(M^{-1/2})$ .

How do we sample from an arbitrary distribution  $p(X)$ ? The idea is to first make an educated choice of a Markov Chain with the prescribed stationary distribution from which we ultimately desire to sample from,  $p(X)$ . After a sufficiently high number of steps, a Markov Chain Monte Carlo (MCMC) algorithm generates samples from the target distribution. Imposing some conditions on this Markov

Chain, namely that it should be irreducible, aperiodic and positive recurrent, the ergodic theorem guarantees that the empirical measures of the aforementioned sampler approach the target stationary distribution. Another important condition to impose on this Markov Chain is detailed balance. Let the transition matrix be  $\mathbf{P} = [p_{ij}]$ , and the state space  $\Omega$  be  $\{\pi_i | i = 1, \dots, |\Omega|\}$ , where  $|\Omega|$  is the total number of possible states. Then, the condition of detailed balance is defined for all  $i, j$  as

$$\pi_i p_{ij} = p_{ji} \pi_j \quad (1.4)$$

Crucially, Monte Carlo methods employ *importance sampling*. It turns out that we can improve upon our estimate of  $\mathbb{E}[f(X)]$  by introducing a separate distribution  $q(x)$ , and defining the weight function as  $w(x) = p(x)/q(x)$ . Then, we can rewrite equation (1.1):

$$\mathbb{E}[f(X)] = \int dx f(x) q(x) w(x) = \mathbb{E}[f(Y) w(Y)], \quad (1.5)$$

with  $Y \sim q$ , i.e. the random variable  $Y$  follows the distribution  $q(Y)$

It appears as though we didn't gain anything. However, by choosing  $q$  wisely, we can actually reduce the variance we computed in equation (1.3):

$$\text{Var}\left(\frac{1}{M} \sum_{k=1}^M f(y_k) w(y_k)\right) = \frac{1}{M} \text{Var}\left(f(y_1) w(y_1)\right) \quad (1.6)$$

Since we didn't make any assumptions about  $q(Y)$ , it may be chosen so as to minimize the variance, hence the error of the Monte Carlo estimator, improving the approximation of the expectation. However, note that the error remains of order  $\mathcal{O}(\frac{1}{\sqrt{M}})$ .

The idea of the Quantum (Classical) Monte Carlo method is to simulate the random quantum (thermal) fluctuations of the system, as it oscillates between states in a given time frame [Newman1999]. Instead of visiting these states uniformly, the algorithm applies *importance sampling*: the most relevant part of the phase space is sampled more frequently, overcoming the seemingly exponential complexity of computing a sample mean numerically. Even though only a small fraction of the system's states are sampled, we obtain an accurate estimate of physical quantities of interest, namely energy, and correlation functions.

QMC generally provides an accurate approximation of the solution to the quantum many-body problem. When relativistic effects are negligible, which is the case of most condensed matter systems, any physical system can be described by a many-body Schrödinger equation. The issue is that the many-body wave function lives in the corresponding Hilbert space that is exponentially large in the number of particles. For example, the number of possible states of a physical system whose configuration space rests on a two-dimensional lattice is exponentially large. The method described above is applied to approximate the multidimensional integrals arising upon formulating the quantum many-body problem in this space.

One can set up a naïve mean field theory in which the many body wave function is approximated by an antisymmetric function of one body wave functions<sup>6</sup>. One of the drawbacks of this approach is that

---

<sup>6</sup>This corresponds to the Hartree-Fock approximation that we used to derive the Hubbard Hamiltonian in section

the effect of correlations is not captured. Fermionic QMC goes beyond mean field theory, capturing the phenomena occurring within strongly correlated electronic systems. For non-frustrated boson systems, a polynomially scaling algorithm leads to an exact solution. For a fermionic system, such as the TMD nanoribbon, the existing algorithms usually provide accurate yet not exact solutions, which would in general require exponential computing time. This is due to the so called sign problem. We will discuss this numerical issue later.

## 1.4 Variational Monte Carlo

Variational techniques rely on an educated guess for the wave function of the system. One often introduces a set of variational parameters  $\alpha$  that are then tuned according to a variational principle. We use the optimized trial wave function to compute physical quantities of interest using Monte Carlo. Note that the method requires prior knowledge about the system. We will see that it is natural to combine the Metropolis algorithm for quantum many-body systems with the variational principle.

A particularly relevant observable is the variational energy  $E_V$  associated with a given quantum state. Let  $\mathbf{r}$  be the  $3N$  spatial coordinates of the  $N$  electrons. Given the Hamiltonian of the system  $\mathcal{H}$ , and a trial wave function  $\psi(\mathbf{r})$  - hopefully a good guess of the wave function representing some state of the system - one can compute the variational energy.

$$E_V = \frac{\langle \psi | \mathcal{H} | \psi \rangle}{\langle \psi | \psi \rangle} = \frac{\int d\mathbf{r} |\psi(\mathbf{r})|^2 E_L(\mathbf{r})}{\int d\mathbf{r} |\psi(\mathbf{r})|^2} = \int d\mathbf{r} \rho(\mathbf{r}) E_L(\mathbf{r}), \quad (1.7)$$

where the local energy  $E_L(\mathbf{r})$  is defined as

$$E_L = \frac{\mathcal{H}\psi(\mathbf{r})}{\psi(\mathbf{r})} \quad (1.8)$$

and the probability distribution  $\rho(\mathbf{r})$  is defined as

$$\rho(\mathbf{r}) = \frac{|\psi(\mathbf{r})|^2}{\int d\mathbf{r}' |\psi(\mathbf{r}')|^2} \quad (1.9)$$

Note that we managed to recast the variational energy as an average of the *local* energy,  $\langle E_L \rangle$ , over the the distribution  $\rho$ . This is easily estimated by sampling  $M$  points  $\mathbf{r}_k$  from  $\rho(\mathbf{r})$ :

$$E_V \approx \bar{E}_L = \frac{1}{M} \sum_{k=1}^M E_L(\mathbf{r}_k), \quad (1.10)$$

where  $\bar{X}$  denotes a sample mean of the random variable  $X$ . A common sampling scheme is the Metropolis-Hastings algorithm.

How do we optimize a variational state? Suppose we are particularly interested in the ground state energy  $E_0$ . Then, the variational principle reads

$$E_{0V}[\alpha_i] = \frac{\langle \psi_0 | \mathcal{H} | \psi_0 \rangle}{\langle \psi_0 | \psi_0 \rangle} \geq E_0, \quad (1.11)$$

where  $\psi_0$  is the ground state wave function. By varying  $\alpha$  we aim to obtain a variational energy that is as close as possible to the true ground state energy. Since  $E_{0V}(\alpha)$  is bounded from below, this is equivalent to minimizing it in the hope that  $E_{0V}(\alpha_{min}) \gtrsim E_0$

The use of an approximate wave function introduces a systematic error. The finite sampling size  $M$ , however, introduces a statistical uncertainty common to all Monte Carlo methods.

### 1.4.1 Variational Techniques

It is natural to combine the Metropolis algorithm for quantum many-body systems with a variational principle. The goal is to find a variational wave function which can be optimized so that ultimately we obtain as accurate as possible an estimate of the ground state of the system [**tao**].

The parameters  $\alpha$  of a trial wave function  $\phi(\mathbf{r})$  are optimized according to the variational principle

$$E[\alpha_i] = \frac{\langle \phi | \mathcal{H} | \phi \rangle}{\langle \phi | \phi \rangle} \geq E_0, \quad (1.12)$$

where  $E_0$  is the ground state energy.

In fact, expanding in terms of the eigenstates of the hamiltonian  $\{\psi_n(\mathbf{r})\}$ , a complete basis set:

$$\phi(\mathbf{r}) = \sum_{n=0}^{\infty} a_n \psi_n(\mathbf{r}), \quad (1.13)$$

and plugging it back into the variational principle, subject to  $E_n \geq E_0$ ,  $n > 0$  and  $\langle \psi_n | \psi_m \rangle = \delta_{nm}$  we obtain

$$E[\alpha_i] = \frac{\sum_n a_n^2 E_n}{\sum_n a_n^2} \geq E_0 \quad (1.14)$$

The expectation is the integral

$$E[\alpha_i] = \frac{\int \phi^*(\mathbf{r}) \mathcal{H} \phi(\mathbf{r}) d\mathbf{r}}{\int |\phi(\mathbf{r}')|^2 d\mathbf{r}'} \equiv \int W(\mathbf{r}) E(\mathbf{r}) d\mathbf{r}, \quad (1.15)$$

where the integrand is a quantity which may be regarded as a distribution function  $W(\mathbf{r}) = \frac{|\phi(\mathbf{r})|^2}{\int |\phi(\mathbf{r}')|^2 d\mathbf{r}'}$  and a local energy of the system at configuration  $\mathbf{r}$ :  $E(\mathbf{r}) = \frac{\mathcal{H}\phi(\mathbf{r})}{\phi(\mathbf{r})}$ .

Given  $W(\mathbf{r})$  and  $E(\mathbf{r})$ , one can in principle evaluate  $E[\alpha_i]$ . In practice  $\phi(\mathbf{r})$  is parametrized depending on the physical model at play, and the variational parameters  $\alpha_i$  in the trial wave function are optimized by minimizing  $E[\alpha_i]$ .

The Metropolis algorithm is used to sample a set of points  $\{\mathbf{r}_i\}$  from the configuration space, and the evaluation of the expectation value  $E[\alpha_i]$  in each QMC step for each set of variational parameters is the equivalent of computing an average of a classical quantity at a given temperature in classical Monte Carlo. Systematically, we optimize the wave function based on the Euler-Lagrange equation

$$\frac{\delta E[\alpha_i]}{\delta \alpha_j} = 0 \quad (1.16)$$

An example of a thorough discussion on the systematic procedure to do this is given in [**umrigar**].

An important aspect of the variational wave function - hopefully an already reasonable approximation of the ground state - is that it should be stable when two particles approach each other and the interaction diverges. This divergence is commonly canceled by their relative kinetic energy when their separation goes to zero - *cusp condition*[mahan]. Building this condition into the variational wave function significantly reduces fluctuations in the results, yielding larger accuracy when dealing with systems with a larger number of particles.

### 1.4.2 Diffusion Monte Carlo

Variational Monte Carlo is limited by the use of a trial wave function  $\phi(\mathbf{r})$ : we may not have enough information to even construct a reliable variational wave function in the first place. [tao]

Diffusion QMC allows the simulation of a many-body system while having only a limited knowledge of the system's physical properties. While it is exact for many-boson systems, it is only approximate for many-fermion systems. The idea is to map the Schrödinger equation into an imaginary-time diffusion equation. Excited states are then filtered out by a diffusion process as time passes. In imaginary-time  $\tau = -it$ , the solution to Schrödinger's equation in terms of a formal series expansion in the eigenfunctions of the hamiltonian becomes a series of transients  $e^{-E_n\tau}$ ,  $n \in \mathbb{N}$ . The longest lasting of these is the ground state. [kosztin]

The idea of DQMC is to generate samples using the exact ground state wave function  $\phi_0(\mathbf{r})$  [vmc]. The associated exact energy  $E_0$  is the matrix element of the hamiltonian calculated using a trial wave function and the ground state wave function.

$$\begin{aligned} E_0 &= \frac{\langle \phi_0 | E_0 \mathbb{1} | \phi \rangle}{\langle \phi_0 | \phi \rangle} = \\ &= \frac{\langle \phi_0 | \mathcal{H} | \phi \rangle}{\langle \phi_0 | \phi \rangle} = \frac{\int d\mathbf{r} \phi_0^*(\mathbf{r}) \phi(\mathbf{r}) E_L(\mathbf{r})}{\int d\mathbf{r} \phi_0^*(\mathbf{r}) \phi(\mathbf{r})} \end{aligned} \quad (1.17)$$

Note that using this trick we avoid the computation of  $\mathcal{H}\phi_0 = E_0\phi_0$ , that is, the ground state energy. Instead, we approximate the integral by considering  $N$  configuration samples  $\mathbf{r}_{k=1,\dots,N}$  in a similar spirit to that of VQMC. Notice that the integral consists of a local energy of the trial wave function  $E_L(\mathbf{r}) = \frac{\mathcal{H}\phi(\mathbf{r})}{\phi(\mathbf{r})}$  averaged over a mixed distribution from which we draw a sample of points  $\mathbf{r}_{k=1,\dots,N}$ .

$$f(\mathbf{r}) = \frac{\phi_0^*(\mathbf{r}) \phi(\mathbf{r})}{\int d\mathbf{r} \phi_0(\mathbf{r}) \phi(\mathbf{r})} \quad (1.18)$$

Take a single particle in 1D. Performing a Wick rotation - effectively going to imaginary time - and shifting the energy, Schrödinger's equation becomes

$$\partial_\tau \psi = -\frac{1}{2m} \partial_x^2 \psi - \left[ V(x) - E_T \right] \psi \quad (1.19)$$

The exact ground state wave function  $\phi_0$  is obtained as the longest lasting transient state in imaginary time; we are interested in the asymptotic behavior of the series expansion constituting the

formal solution of Schrödinger's equation

$$\psi(x, \tau) = \sum_{n=0}^{\infty} c_n \Phi_n(x) e^{-(E_n - E_T)\tau} \quad (1.20)$$

Imaginary time evolution is governed by

$$\begin{aligned} |\psi(t)\rangle &= \lim_{\tau \rightarrow \infty} \sum_i e^{-(E_i - E_T)\tau} |\psi_i\rangle \langle \psi_i| \psi \rangle = \\ &= \lim_{\tau \rightarrow \infty} e^{-(E_0 - E_T)\tau} |\phi_0\rangle \langle \phi_0| \psi \rangle \end{aligned} \quad (1.21)$$

If  $E_T > E_0$  the wave function diverges exponentially fast:  $\lim_{\tau \rightarrow \infty} \psi(x, \tau) = \infty$ . Similarly, for  $E_T < E_0$  it vanishes exponentially fast:  $\lim_{\tau \rightarrow \infty} \psi(x, \tau) = 0$ . However, if  $E_T = E_0$  the wave function converges to the ground state one up to a constant factor.

$$\lim_{\tau \rightarrow \infty} \psi(x, \tau) = c_0 \phi_0(x) , \text{ or } \lim_{\tau \rightarrow \infty} |\psi(\tau)\rangle \propto |\phi_0\rangle \quad (1.22)$$

DQMC makes use of equation (1.22), approximating  $\phi_0(x)$  by  $\psi(x, \tau)$  for sufficiently long time. The only requirement is that  $\psi(x, \tau)$  and  $\phi_0(x)$  overlap significantly so that  $c_0$  is large enough to be numerically measurable, and we can always center a positive trial wave function in a region where  $\phi_0(x)$  is large enough. This is always possible for a single particle, but note that it might fail for a many-fermion system for which the wave function crosses a number of nodes due to its antisymmetric nature.

### 1.4.3 Path Integral Formulation

**A –** In position representation, we may rewrite equation (1.21) by noting that

$$\psi(\mathbf{r}_f, \tau) = \int d\mathbf{r}_i G(\mathbf{r}_f | \mathbf{r}_i; \tau) \psi(\mathbf{r}_i), \quad (1.23)$$

where we have defined the Green function  $G(\mathbf{r}_f | \mathbf{r}_i; \tau) \equiv \langle \mathbf{r}_f | e^{-(\mathcal{H} - E_T)\tau} | \mathbf{r}_i \rangle$ , the imaginary-time propagator. This allows for a path integral interpretation of the diffusion method. Take equation (1.23), multiply by  $\psi(\mathbf{r}_f)$  and divide by  $\psi(\mathbf{r}_i)$  to obtain the evolution equation for the mixed distribution  $f(\mathbf{r}, t) = \psi(\mathbf{r}, \tau) \psi(\mathbf{r})$ :

$$f(\mathbf{r}_f, \tau) = \int d\mathbf{r}_i \tilde{G}(\mathbf{r}_f | \mathbf{r}_i; \tau) \psi(\mathbf{r}_i)^2, \quad (1.24)$$

where we have redefined an *importance sampling* Green function  $\tilde{G}(\mathbf{r}_f | \mathbf{r}_i; \tau) = \psi(\mathbf{r}_f) G(\mathbf{r}_f | \mathbf{r}_i; \tau) \frac{1}{\psi(\mathbf{r}_i)}$ .

The mixed distribution approaches the target stationary distribution:  $f(\mathbf{r}) = \lim_{t \rightarrow \infty} f(\mathbf{r}, t) \propto \phi_0(\mathbf{r}) \psi(\mathbf{r})$

In the limit of short propagation time, the action of the  $\hat{T}$  and  $\hat{V}$ , the kinetic and potential energy operators, does not significantly change the states acted upon separated by the short interval  $t$ :  $|\chi(t')\rangle$  and  $|\chi(t' + t)\rangle$ . Furthermore, one can use the Trotter-Suzuki decomposition, based on the result that for a - not necessarily commuting - set of operators  $\{A_i | i = 1, \dots, p\}$  we can write

$$e^{A_1+A_2+\dots+A_p} = \lim_{m \rightarrow \infty} (e^{A_1/m} e^{A_2/m} \dots e^{A_p/m})^m \quad (1.25)$$

In this case it allows us to rewrite  $e^{-(\hat{T}+\hat{V})t} = e^{-\hat{V}t/2} e^{-\hat{T}t} e^{-\hat{V}t/2} + \mathcal{O}(t^3)$ . Further acting with the potential operator on the left and on the right, we find an analytical expression for the propagator.

$$G(\mathbf{r}_f|\mathbf{r}_i; \tau) \approx \frac{e^{-\frac{(\mathbf{r}_f - \mathbf{r}_i)^2}{2t} - \left(\frac{V(\mathbf{r}_f) + V(\mathbf{r}_i)}{2} - E_T\right)t}}{(2\pi t)^{3N/2}} \quad (1.26)$$

The *fermion sign problem* will shortly become apparent. The key assumption that breaks for many-fermion wave functions is that the trial wave function does not change sign so that  $\psi(\mathbf{r}_f)/\psi(\mathbf{r}_i) > 0$ . In the latter case, the short time *importance sampling* Green function becomes

$$\tilde{G}(\mathbf{r}_f|\mathbf{r}_i; \tau) \approx \frac{1}{(2\pi t)^{3N/2}} e^{-\frac{(\mathbf{r}_f - \mathbf{r}_i - \mathbf{v}(\mathbf{r}_i)t)^2}{2t}} e^{-\left(\frac{E_L(\mathbf{r}_f) + E_L(\mathbf{r}_i)}{2} - E_T\right)t}, \quad (1.27)$$

where we introduced two quantities assumed to be constant in the short time interval: the drift velocity  $\mathbf{v}(\mathbf{r}) = \nabla\psi(\mathbf{r})/\psi(\mathbf{r})$ , and the local energy  $E_L(\mathbf{r}) = \psi(\mathbf{r})^{-1}\mathcal{H}\psi(\mathbf{r})$ . This approximation implies a finite step error that vanishes in the  $t \rightarrow 0$  limit. Note that this is a solution analogous to that of a diffusion process with a drift term biasing the Brownian motion in configuration space. In practice, we obtain the stationary distribution, simulating the time evolution by iterating

$$f(\mathbf{r}) = \lim_{N \rightarrow \infty} \int d\mathbf{r}_1 d\mathbf{r}_2 \dots d\mathbf{r}_N \tilde{G}(\mathbf{r}|\mathbf{r}_N; t) \tilde{G}(\mathbf{r}_N|\mathbf{r}_{N-1}; t) \dots \tilde{G}(\mathbf{r}_2|\mathbf{r}_1; t) \psi(\mathbf{r}_1)^2, \quad (1.28)$$

but the time evolution of  $f$  can equivalently be shown to be given by a diffusion equation (it is done in **[vmc\_review]**):  $\partial_t f = -\mathcal{L}f - (E_L(\mathbf{r}) - E_T)f$ , where we have defined the Fokker-Planck operator  $\mathcal{L} = -\frac{1}{2}\nabla^2 + \nabla \cdot \mathbf{v}(\mathbf{r})$ .

The stochastic realization aiming at estimating the integral in equation (1.28) is slightly more cumbersome. The Green function  $\tilde{G}(\mathbf{r}_f|\mathbf{r}_i; t)$  is not a stochastic matrix. Probability density normalization is not preserved:  $\int d\mathbf{r}_f \tilde{G}(\mathbf{r}_f|\mathbf{r}_i; t) \neq 1$ .

However, it may be written as the product of a stochastic matrix  $P$  and a weight matrix  $W$ :  $P(\mathbf{r}_f|\mathbf{r}_i)W(\mathbf{r}_f|\mathbf{r}_i)$ .

$$P(\mathbf{r}_f|\mathbf{r}_i) = (2\pi t)^{-\frac{3N}{2}} \exp \left[ -(\mathbf{r}_f - \mathbf{r}_i - \mathbf{v}(\mathbf{r}_i)t)^2 / 2t \right] \\ W(\mathbf{r}_f|\mathbf{r}_i) = \exp \left[ [(E_L(\mathbf{r}_f) + E_L(\mathbf{r}_i))/2 - E_T]t \right], \quad (1.29)$$

corresponding to a *weighted random walk*. In GFQMC, one further reformulates the diffusion process so that no systematic errors due to the finite time interval  $t$  arise. At each iteration  $k$ , a population of  $M_k$  walkers at  $\mathbf{r}_{k,\alpha}$  with weights  $w_{k,\alpha}$  perform random walks with a branching or birth-death process

in which the weights  $w_{k,\alpha}$  vary only in a small range from walker to walker over the same iteration and from iteration to iteration. Under certain conditions, sampling from the correct distribution is ensured.

#### 1.4.4 Fixed-Node, Constrained Path QMC for Many-Fermion systems

For many-fermion systems the condition of antisymmetry of the wave function may not in general be satisfied due to the finite sampling in position space. If the many-fermion wave function has nodes, a bosonic state of lower energy always exists. This means that the target ground state becomes a bosonic one for which  $\psi_B(\mathbf{r})$  can be chosen strictly positive.

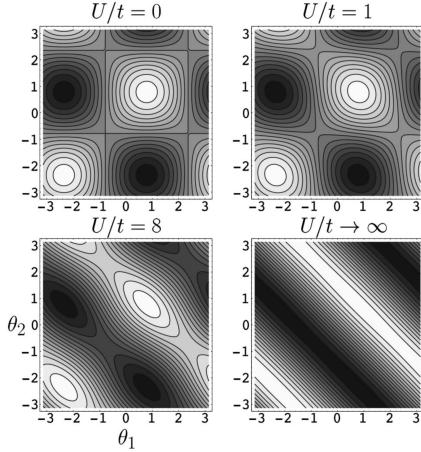

By iteratively applying the Green function exactly,  $\psi(\mathbf{r})^2$  now converges to  $\phi_0(\mathbf{r})\psi(\mathbf{r})$ . This is because the trial wave function  $\psi(\mathbf{r})$  is antisymmetric and has zero overlap with the symmetric bosonic states. Finite sampling leads to the appearance of a growing and eventually dominating bosonic component  $\psi_B$ .

Now suppose you impose antisymmetry by eliminating bosonic states, i.e. considering all electron permutations in each walker. In this fermionic subspace, different paths between the same endpoints can contribute with opposite sign:  $-\phi_0$  is also a solution of the Schrödinger equation. Both are sampled with approximately equal probability for large enough iteration time and positive and negative weight contributions cancel out - another manifestation of the sign problem.

Two methods that modify DQMC to correct for the sign problem are the fixed-node approximation [**constrained2**, **vmc\_review**] and constrained path QMC [**constrained**, **constrained2**]. The idea of the former is to force convergence to a wave function approximating the Fermionic ground state by fixing its nodes to be the same as those of the trial wave function [**vmc\_review**]. One repeats the procedure developed in the previous section for a formally defined hamiltonian  $\mathcal{H}_{FN}$ , which is simply the former hamiltonian with infinite potential barriers at the nodes of  $\psi(\mathbf{r})$ . The energy associated with  $\mathcal{H}_{FN}$  is an upper bound on the true ground state energy. Thus, the accuracy of this method depends on the shape of the nodal surface of the trial wave function. On the other hand, in constrained path QMC the ground state is represented by  $|\phi_0\rangle = \sum_\chi c_\chi |\chi\rangle$ , where the Slater determinants  $|\chi\rangle$  are chosen so that  $c_\chi > 0$ . Note that this is not a unique decomposition. A constraint is placed on the random walks to account for the change to the Slater determinant basis. The two regions where the overlap  $\langle\psi_T|\chi\rangle$  is either positive or negative, causing the sign problem, are not distinguishable. The approximation consists of breaking this symmetry so that the random walks are constrained to the region  $\langle\psi_T|\chi\rangle > 0$ .

#### 1.4.5 Determinantal/Auxiliary Field QMC

**B –** The idea of this method is establish a mapping between quantum and classical Monte Carlo, using a suitable change of variables. The random variables are then sampled from the configuration space of the corresponding classical problem. The price to pay is that for a d-dimensional quantum problem, the corresponding classical problem is  $(d + 1)$ -dimensional: an additional degree of freedom is added, and as we will show it corresponds to an imaginary time.

**Figure 1.4:** Contour plots of the two-fermion ground state wave function overlap  $\langle \chi | \phi_0 \rangle$  for a Hubbard model as obtained in [constrained2]. The parameters  $\theta_{1,2}$  arise from the decomposition  $|\chi\rangle = (\cos\theta_1 c_{1\uparrow}^\dagger + \sin\theta_1 c_{2\uparrow}^\dagger)(\cos\theta_2 c_{1\downarrow}^\dagger + \sin\theta_2 c_{2\downarrow}^\dagger)$ , where  $c^{(\dagger)}$  are annihilation (creation) operators of two fermions with either spin up or down. Notice the varying nodal surfaces as the interaction energy-hopping parameter ratio varies. The accuracy of the constrained path QMC method depends on the shape of these surfaces (taken from [constrained2]).

The expected value of a physical observable  $\mathcal{O}$  may be written as  $\langle \mathcal{O} \rangle = \text{Tr}(\mathcal{O}\mathcal{P})$ , where we have defined a projection operator

$$\mathcal{P} = \frac{1}{Z} e^{-\beta\mathcal{H}}, Z = \text{Tr}(e^{-\beta\mathcal{H}}) = \sum_i \langle \psi_i | e^{-\beta\mathcal{H}} | \psi_i \rangle, \quad (1.30)$$

and the trace is taken over the Hilbert space describing all possible occupations in a lattice model.

Finding an approximation to the projection operator which is amenable to computation is done in terms of the Hubbard-Stratonovich transformation: the problem is reformulated in terms of auxiliary variables  $h_i$ . The set  $\{h_i\}$  is known as the Hubbard-Stratonovich field.

In the end, we sample configurations, that is, particular realizations of the HS field, with probability  $P(h)$ . It is the computation of this probability that requires determinant calculations giving the name to the method. For concreteness, we state without proof that for the example of the Hubbard model we have:

$$P(h) = \frac{\eta_d}{Z_h} \det[M_+(h)] \det[M_-(h)], \quad (1.31)$$

where  $M_\sigma(h)$  are fermion matrices depending on the imaginary time frame, spin, and the HS field;  $\eta_d$  is simply a normalization constant depending on dimension, and  $Z_h$  is the partition function expressed in terms of the HS field [qmc].

To move from a configuration  $\{h\}$  to a new one  $\{h'\}$ , we vary, or flip, the value of only one variable  $h_i$ , leaving the rest unchanged. We use an acceptance-rejection scheme - the Metropolis-Hastings algorithm - that ensures that the accepted sample configuration follows the desired distribution. Once we reach equilibrium, i.e. the Markov Chain hits the stationary distribution, we have finished the so called warm up steps, and we may start measuring.

Recall the reasoning that was made in section 1.4.2. The solution of the Schrödinger equation may

be expressed in terms of a linear combination of stationary states, which depend on time via a factor  $e^{-iE_n t}$ , where  $n$  labels the energy level of the quantum system under study. We choose the energy scale so that all energies are positive and perform a change of variable to imaginary time  $t = -i\tau$ . The solution's time dependence is now described by a sum of transients  $e^{-E_n \tau}$ ,  $n \in \mathbb{N}$ , and by following the (imaginary) time evolution of the wave function long enough, we will asymptotically reach the ground state energy  $E_0$ , and its corresponding wave function  $\phi_0$ . Note that this is independent of the initial condition in which we prepare the system. Convergence speed may eventually depend on this choice, but from a mathematical point of view if we wait long enough only the ground state will survive. The imaginary time many-body propagator  $U(\tau) = e^{-H\tau}$  filters a trial wave function  $\phi$  to the exact ground state  $\phi_0$ :

$$E_0 = \lim_{\tau \rightarrow \infty} \frac{\langle \phi | H U(\tau) | \phi \rangle}{\langle \phi | U(\tau) | \phi \rangle} \quad (1.32)$$

We impose the condition that  $\phi$  mustn't be orthogonal to  $\phi_0$ . Additionally, we require  $\phi$  to be a symmetrized (antisymmetrized) product of single-particle orbitals for bosons (fermions).

The method can be used to treat systems with a variety of interactions. In general:

$$\mathcal{H} = \sum_{\alpha\beta} K_{\alpha\beta} \rho_{\beta\alpha} + \frac{1}{2} \sum_{\alpha\beta\gamma\delta} v_{\alpha\beta\gamma\delta} \rho_{\gamma\alpha} \rho_{\delta\beta}, \quad (1.33)$$

where  $\rho_{\beta\alpha} \equiv a_\alpha^\dagger a_\beta$  and  $K_{\alpha\beta} = T_{\alpha\beta} \pm \frac{1}{2} \sum_\gamma v_{\alpha\gamma\gamma\beta}$  is the kinetic energy  $T$  plus a self-interaction term for bosons or fermions, respectively. The subscripts  $\alpha, \beta, \gamma, \delta$  represent eventually present degrees of freedom: spin, isospin, etc., as well as spatial coordinates [sugiyama].

We introduce an auxiliary field  $h$  that reduces the exponential of the two-body operator in equation (1.33) to a functional integral over an infinite set of exponentials of one-body operators. We then run Monte Carlo to approximate these integrals. A valuable property of AFQMC is that it properly treats fermions: the HS representation of the propagator affords a description in terms of single-particle exactly antisymmetrized wave functions. GFQMC and DQMC do not share this property.

The long time behavior of a trial state:  $\lim_{\tau \rightarrow \infty} e^{-\tau(\mathcal{H}-\varepsilon_0)} |\psi_T\rangle = |\phi_0\rangle \langle \phi_0 | \psi_T \rangle$  may be mapped onto a stochastic process in the manifold of  $N$ -particle Slater determinants  $\mathcal{D}(N)$  [zhang]. The mapping to a stochastic process is made possible by the discretization

$$e^{-\tau(\mathcal{H}-\varepsilon_0)} = (e^{-\delta\tau(\mathcal{H}-\varepsilon_0)})^n \quad \text{with} \quad \delta\tau = \frac{\tau}{n} \quad (1.34)$$

The HS transformation is in fact an operator identity that allows the establishment of a formal correspondence between a system of interacting fermions and an ensemble of non interacting fermion systems coupled to fluctuating external potentials. This leads to a random walk representation of the imaginary time evolution.

A limitation of the straightforward numerical implementation of AFQMC is that it leads to an exponential increase in statistical errors with imaginary time. This is due to the appearance of random complex phases during the evolution. To solve this problem, S. Zhang introduced an importance sam-

pling transformation guiding the random walk [**zphase**] . This is done by introducing shift parameters in terms of which we rewrite  $e^{-n\delta\tau(\mathcal{H}-\varepsilon_0)}|\psi_T\rangle$ . These parameters are chosen to minimize fluctuations in the importance function to first order in  $\delta\tau$ .

The aim is to solve the sign problem which arises when the overlap between one or more walkers and the trial state vanishes, yielding large fluctuations in the importance function, and generating statistical errors in AFQMC's estimates.

#### 1.4.6 Computational Complexity and the Sign Problem

The sign problem afflicting many-fermion QMC causes an exponential increase of the computing time with the number of particles. A polynomially scaling algorithm would provide an unbiased and numerically exact solution (as in the case of bosons) for the problem of simulating a strongly correlated electron system. However, the problem was recently shown to be NP hard [**troyer**]. Solving the sign problem would solve all NP problems in polynomial time (proving that  $NP = P$ ) in what would be a major breakthrough in mathematics. This is widely believed to be unlikely, i.e. there is a conjecture that  $NP \neq P$ , although currently no mathematical proof exists of this impossibility.

Specific sign problems might be solvable. This indeed happens for a restricted subclass of quantum systems, for example see [**wiese**, **arnow**, **kalos**]. An interesting open question is that of determining which models allow a partial solution of the sign problem due to their special properties. In particular, it is relevant for this field whether the 2D fermionic Hubbard model belongs to this class or not. A promising idea to circumvent NP hardness is to use ultracold atoms in optical lattices [**optical**], effectively using a quantum simulator to study the phase diagrams of correlated quantum systems. Although promising, even this method may not solve the problem in general: it is also still an open question whether a quantum computer could ever solve the NP complete problem (see [**troyer**] and references therein).

### 1.5 Original Contributions

The major contribution of this work has been the development of a general determinant QMC code in C++, which can be used to simulate low-dimensional Hubbard-like models with different geometries.

The code was then applied to study the properties of a TMD nanoribbon providing insight into its magnetic properties.

Lastly, we characterized and compared different options to stabilize the matrix products needed to perform the simulations.

### 1.6 Thesis Outline

In this thesis, we first aim to review the existing literature on QMC methods for fermions, then become acquainted with some of the existing libraries so as to develop a code to tackle a specific problem of interacting electrons. The second part of this work has to do with the application to TMD nanoribbons and physical interpretation of results. The last phase of this project shall then consist in

performing various measurements using the built QMC code, and interpreting the results in light of the relevant literature.

Review of Classical Monte Carlo

Build benchmarks for simple examples

Review of main 2D materials results and TMD's

Explore relevant QMC methods, start writing thesis

Review open source libraries, namely QUEST, Alps, Monte Python , ALF

Implement QMC code, application to simple models

Determine which are the main quantities to measure for TMD nanoribbons

Implement measurements and test the code on more complex models

Start performing QMC measurements

Compile and interpret results

Finish writing thesis, review and editing

# 2

## Minimal models of electron correlations in energy bands

2.5	Effective Heisenberg Hamiltonian . . . . .	39

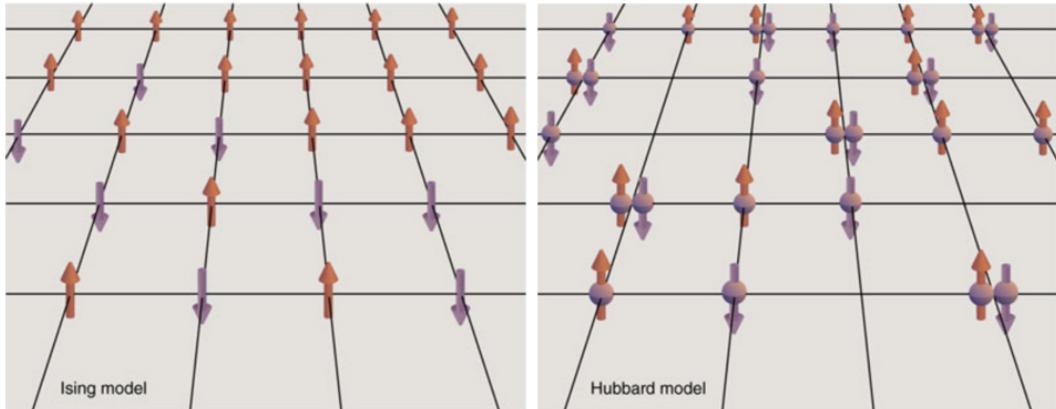

---

We start with an overview of the Hubbard model and in the following chapters we provide details on how to simulate it numerically using Quantum Monte Carlo. In particular, we discuss the original motivation provided by Hubbard to introduce the model and show how its Hamiltonian arises as an approximate representation of the Coulomb repulsion between electrons in a solid. Then, we present exact solutions for particular limiting cases, which will be used to crosscheck our simulations. In particular, we show that, in the limit where the interaction is large, the effective Hamiltonian at half filling corresponds to an atomic Heisenberg model defined in the appropriate Hilbert space with one electron per site.

## 2.1 Modelling electron correlations

The Hubbard model appeared in 1963 as one of the first attempts to include electron interaction effects in a quantum mechanical description of a solid. Originally, it was introduced to explain the behavior of the electrons in the narrow, partially filled  $d$ -bands of transition metals [28]. Correlation phenomena due to the Coulomb repulsion between the electrons in these bands lead to a behavior reminiscent of the atomic picture of a solid. In fact, the model may simply be regarded as a minimal model of interacting electrons in an energy band of a solid, where only on-site interactions are considered. We have come a long way since the introduction of the Hubbard model and it is now arguably as paradigm-defining in many-body theory as the Ising model in statistical physics [45–47].

Although the Hubbard model was initially applied to transition metal monoxides like FeO, NiO, and CoO, which are antiferromagnetic insulators (and not metallic, as was initially thought)<sup>1</sup>, it is a minimal model giving insight on insulating, magnetic, and even superconducting phases arising due to the effect of electron interactions in a variety of quantum systems.

**Figure 2.1:** Unlike the Ising model, where either an up or a down spin live at each site, in the Hubbard model, there are four possible states at each site: a "hole" (absence of an electron), either an up spin electron or a down spin electron, or two electrons of opposite spins. The idea behind the model is to consider that the electrons interact, repelling each other, only the latter case, i.e. when they are on the same site (taken from [48]).

Of course, Figure (2.1) is only a simplified view presented for the sake of analogy. The Hubbard model is actually defined in terms of a Hamiltonian acting on electron wave functions centered in the

<sup>1</sup>They were predicted to be metals by band theory until they were found not to behave like metals empirically.

sites of a lattice. Ultimately, we wish to determine, or at least approximate, the wave function describing the full electronic system. To do so, we must consider a Hamiltonian that allows simultaneous charge and spin fluctuations. It turns out that the *many-body* wave function we seek is not, in general, a simple combination of products of one electron wave functions, as in the interaction-free case.

When Hubbard's seminal paper came out, it followed a trend that arose in the 1950's when people were working on a theory of correlation effects in the free electron gas [49–54]. Hubbard devised a simple model for the (at the time) seemingly intractable problem of interacting electrons in a band. His work explained qualitatively some properties of compounds containing transition metals, in which electron correlations are non negligible. It turns out that the mathematical formulation of the interaction problem for correlated electrons in a band is not prohibitively complicated, and is relatively amenable to both analytical and numerical computations after some reasonable approximations are introduced. Notably, the model is particularly adapted to computer simulations because of its simple approximate Hamiltonian. Moreover, it has been shown to be very relevant in the description of Mott insulators, and high  $T_c$  superconductors<sup>2</sup>. In fact, the Hubbard model has found many applications, describing successfully a variety of quantum systems [55]; nonetheless, even the simplified picture it offers is in general difficult to approach analytically. There exists an exact, albeit not very transparent solution in one dimension via Bethe ansatz [27], however the more general higher dimensional case is often solved numerically. An example of particular relevance for the work of this thesis is the study carried out by Hirsch [7]. In the following chapters, we will discuss how to simulate the Hubbard model using a numerical approach that is based on this seminal paper, and essentially follows the ideas introduced in it.

## 2.2 Hubbard model

The nearly free electron gas models the conduction bands of metals and alloys fairly accurately. The high mobility of the electrons compared to the ions justifies two equivalent approximations, both giving essentially the same results [56]. The first idea is to treat the periodic potential created by the *virtually* fixed ions (compared to the electrons) as a perturbation on the free electron gas. Equivalently, we may imagine the system as a collection of tightly bond atoms, in which the electrons in the higher energy band hop from atom to atom. Both these approaches lead to band theory, a framework which allows us to predict whether a material is a conductor or a insulator. From the tight binding point of view, the effect of the electron mobility is the broadening of the atomic energy levels: the electrons in the solid occupy energy bands, rather than levels. The partially filled band of highest energy is called the conduction band, since it is the band occupied by conduction electrons hopping from atom to atom. However, in transition metal and rare-earths, as in some compounds containing these elements, apart from the conduction bands there are partially filled bands:  $d$ – or  $f$ –bands. The partial filling of these bands and the electron correlations within them are responsible for the characteristic properties of these solids. Some of these properties are not explained by band theory, namely the Mott metal-insulator

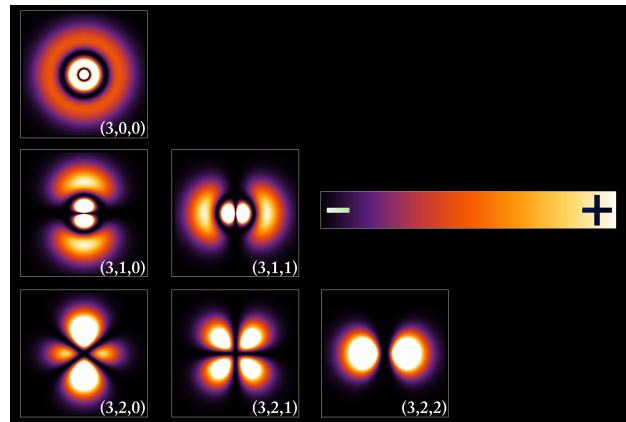

---

<sup>2</sup>In this context,  $T_c$  is the critical temperature associated with the transition to a superconducting phase.

transition [57–59].

### 2.2.1 Electron correlations in narrow $d$ –bands

First, note that the effects of correlations cannot possibly be the same in narrow energy bands and in the free electron gas. To see this, we may simply recall the shape of a  $d$ –wave function. In a  $d$ –orbital, the electron charge density is concentrated near the nucleus. In a solid, the electronic charge density should then also be concentrated near the nuclei, as long as the atomic description is useful, even if not completely correct<sup>3</sup>. It is much smaller between atoms so that electrons do seem to belong to individual atoms in some sense. For a  $d$ –band, we assume this description to hold to some extent since the band is narrow. Thus, the fact that we may speak with some meaning of an electron belonging to a particular atom motivates a description from which the atomic characteristics of the solid emerge, in spite of the fact that the bandwidth of a  $d$ –band is still appreciable. The point is that electrons in  $d$ –bands are certainly not well described by a free electron gas, which cannot possibly account for atomic-like behavior.

**Figure 2.2:** Probability density plots for different hydrogen orbital wave functions corresponding to quantum numbers  $(n, l, m)$  for  $n = 3$ .  $d$ -wave functions correspond to  $l = 2$ . Note that the probability density is always higher in a region near the nucleus, and has a complicated shape, which will lead to a non-uniform distribution of electronic charge, as opposed to the case of the free electron gas. (adapted from [60])

Experimentally,  $d$ –electrons of transition metals show a hybrid behavior: sometimes they are accurately described by an ordinary band model, but there are occasions in which the atomic model is better. For example, we see spin wave phenomena in ferromagnetic transition metals, and the susceptibilities of some of these metals depend strongly on temperature. This is characteristic of an atomic (Heisenberg) model. On the other hand, the  $d$ –electrons contribute significantly to the low temperature specific heat and sometimes the magnetic moments per atom of some transition metal ferromagnets are not integer multiples of the Bohr magneton. This is characteristic of band theory<sup>4</sup>.

<sup>3</sup>The electronic charge density is, of course, not actually defined in terms of a squared norm of the  $d$ –wave function for a narrow band. There is some broadening of the corresponding atomic energy level, and the wave function describing an electron is a Bloch wave function. Since the band is narrow, we assume that the atomic wave function description is still somewhat useful in a given range and we use it to provide a heuristic motivation for the non validity of the free electron assumption.

<sup>4</sup>Think, for example, of a tight binding model. Electrons hop from atom to atom, and in general the spin of each atom depends on the particular electrons “belonging” to it at a given time. If we take an average of the total spin of each atom, we will in general not necessarily obtain an integer multiple of the Bohr magneton. If we simply had a collection of atoms, Hund’s rule would apply, and each atom would have its spin aligned in a given direction. The average spin

Our theory of correlations should describe this balance between band-like and atomic-like behavior.

The atomic picture of a solid consists of an electron gas where ions are immersed. The ions then interact in much the same way as they do in salts. This extreme scenario is surely not even close to the true state of affairs since the number of  $d$ -electrons per atom is in general not an integer. This motivates us to introduce a less restrictive model, which is not too far from the atomic model. We shall assume that while  $d$ -electrons still have some band motion, they are strongly correlated with each other so that the metal retains some atomic-like behavior. The correlations between electrons on different atoms are likely much weaker and we neglect them.

Let us now look at an example of the aforementioned circumstance. Take a partially filled  $d$ -band of non-interacting electrons. The spin of any given atom in the solid is just the total spin of all electrons on that atom. It fluctuates both in magnitude and in direction, with a characteristic time that depends on how frequently  $d$ -electrons hop. We can estimate the time interval between  $d$ -electron hopping events between atoms as a being of the order  $\hbar/\Delta$ , where  $\Delta$  is the  $d$ -electron bandwidth. The spin can thus be thought of as being associated to each individual (and constantly hopping)  $d$ -electron.

How do the electron interactions affect this picture? We start by recalling Hund's rule: the nature of the interactions between atoms leads to an alignment of the spins on each atom. Since the atomic picture seems to prevail in our metal, we have reason to expect a similar effect to occur. An atom with a total spin in some direction at a given time will tend to attract electrons with the spin on that direction and repel those with opposite spin. This mechanism makes it unlikely for the spin of an atom to change much over time.

If the interactions between atoms are strong enough, the correlations become considerable, and to state it more precisely, the total spin of an atom will persist for a time that is long compared with the  $d$ -electron hopping time. Note that it is not the localization of the electrons that causes the spin state of the atom to persist. The specific electrons belonging to a given atom change all the time as long as their spin is consistent with the total spin requirement imposed by Hund's rule. For strong enough correlations, we may think of the spin as being associated to each atom, which opens up the possibility to describe the system using an atomic (Heisenberg) model, as we shall see later.

A theory of electron correlations in a narrow energy band should reduce to an atomic model in the appropriate limit, for example atoms that are so far apart on a lattice that they interact only very weakly. Although we always keep in mind that we are focusing on  $d$ -electrons, we shall consider  $s$ -electrons in what follows for the sake of simplicity. The important conclusions will not differ significantly. We will use the "atomicity" of the electronic distribution to introduce an approximate representation of the electron interaction. It turns out that this representation is mathematically much simpler to handle than the Coulomb interaction itself.

In short, our picture is the following: electrons hop rapidly from atom to atom in a band-like fashion, but their motion is correlated in such a way that atomic characteristics emerge. The extent of atomic behavior depends, of course, on the strength of the interaction.

---

would then tend to be an integer multiple of the Bohr magneton.

## 2.2.2 Hubbard Hamiltonian

Imagine a hypothetical partially filled narrow  $s$ -band with  $n$  electrons per atom. Suppose you have obtained Bloch wave functions  $\psi_{\mathbf{k}}$  corresponding to energies  $\varepsilon_{\mathbf{k}}$  by solving the Schrödinger equation for some spin-independent Hartree-Fock potential that accounts for the average interaction of the  $s$ -band electrons with electrons on other bands, and the interaction with the other  $s$ -electrons. The electrons on the band evolve according to the Hamiltonian:

$$\begin{aligned} \mathcal{H} = & \sum_{\mathbf{k}\sigma} \varepsilon_{\mathbf{k}} c_{\mathbf{k}\sigma}^\dagger c_{\mathbf{k}\sigma} + \frac{1}{2} \sum_{\substack{\mathbf{k}_1 \mathbf{k}_2 \\ \mathbf{k}'_1 \mathbf{k}'_2 \\ \sigma_1 \sigma_2}} \left\langle \mathbf{k}_1 \mathbf{k}_2 \left| \frac{e^2}{r} \right| \mathbf{k}'_1 \mathbf{k}'_2 \right\rangle c_{\mathbf{k}_1 \sigma_1}^\dagger c_{\mathbf{k}_2 \sigma_2}^\dagger c_{\mathbf{k}'_2 \sigma_2} c_{\mathbf{k}'_1 \sigma_1} \\ & - \sum_{\substack{\mathbf{k} \mathbf{k}' \\ \sigma}} \left[ 2 \left\langle \mathbf{k} \mathbf{k}' \left| \frac{e^2}{r} \right| \mathbf{k} \mathbf{k}' \right\rangle - \left\langle \mathbf{k} \mathbf{k}' \left| \frac{e^2}{r} \right| \mathbf{k}' \mathbf{k} \right\rangle \right] \nu_{\mathbf{k}'} c_{\mathbf{k}\sigma}^\dagger c_{\mathbf{k}\sigma}, \end{aligned} \quad (2.1)$$

where the  $\mathbf{k}$ -sums run over the first Brillouin zone.

The integrals are defined by

$$\left\langle \mathbf{k}_1 \mathbf{k}_2 \left| \frac{e^2}{r} \right| \mathbf{k}'_1 \mathbf{k}'_2 \right\rangle \equiv V_{\mathbf{k}_1 \mathbf{k}_2}^{\mathbf{k}'_1 \mathbf{k}'_2} = e^2 \int \frac{\psi_{\mathbf{k}_1}^*(\mathbf{x}) \psi_{\mathbf{k}'_1}(\mathbf{x}) \psi_{\mathbf{k}_2}^*(\mathbf{x}') \psi_{\mathbf{k}'_2}(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|} d\mathbf{x} d\mathbf{x}' \quad (2.2)$$

The first term represents the band energies of the electrons and the second term represents the interactions among them. The last term subtracts the potential energy of the electrons in the part of the Hartree-Fock field due to the electrons of the  $s$ -band itself. This term ensures that we do not overestimate the magnitude of the interactions between the electrons of the band: the Hartree-Fock field that specifies  $\varepsilon_{\mathbf{k}}$  is computed taking into account these interactions, so if we didn't subtract the last term, we would count the energy of these interactions twice since they reappear in the second term. Furthermore, we assume that up and down spins are occupied equally, and  $\nu_{\mathbf{k}}$  are the occupation numbers of the states of the band in the Hartree-Fock calculation.

The term that we subtract in equation (2.1) corresponds to the part of the interaction term which is already accounted for by the first diagonal mean field term. Thus, it corresponds to the mean field expansion of the interaction term (i.e. the second term), which is generically written

$$V_{\text{int}} = \frac{1}{2} V_{\nu' \mu'}^{\nu \mu} c_{\nu}^\dagger c_{\mu}^\dagger c_{\mu'} c_{\nu'}, \quad (2.3)$$

where the summation over repeated indices is implied.

In appendix A, we obtain the mean field form of  $V_{\text{int}}$  in the Hartree-Fock approximation.

Now consider the Wannier functions

$$\phi(\mathbf{x}) = N^{-1/2} \sum_{\mathbf{k}} \psi_{\mathbf{k}}(\mathbf{x}), \quad (2.4)$$

where  $N$  is the number of atoms.

We may write  $\psi_{\mathbf{k}}$  as a combination of Wannier functions localized at each atom.

$$\psi_{\mathbf{k}}(\mathbf{x}) = N^{-1/2} \sum_i e^{i\mathbf{k}\cdot\mathbf{R}_i} \phi(\mathbf{x} - \mathbf{R}_i), \quad (2.5)$$

where the sum runs over all atomic positions  $\mathbf{R}_i$ .

Introducing the annihilation (creation) operators of an electron of spin  $\sigma$  in the orbital state  $\phi(\mathbf{x} - \mathbf{R}_i)$  (at site  $i$ ),  $c_{i\sigma}^{(\dagger)}$ , we may write

$$c_{\mathbf{k}\sigma}^{(\dagger)} = N^{-1/2} \sum_i e^{i\mathbf{k}\cdot\mathbf{R}_i} c_{i\sigma}^{(\dagger)} \quad (2.6)$$

Thus, the Hamiltonian becomes

$$\begin{aligned} \mathcal{H} = & \sum_{\substack{ij \\ \sigma}} K_{ij} c_{i\sigma}^\dagger c_{j\sigma} + \frac{1}{2} \sum_{\substack{ijkl \\ \sigma\sigma'}} \left\langle ij \left| \frac{e^2}{r} \right| kl \right\rangle c_{i\sigma}^\dagger c_{j\sigma'}^\dagger c_{l\sigma'} c_{k\sigma} \\ & - \sum_{\substack{ijkl \\ \sigma}} \left[ 2 \left\langle ij \left| \frac{e^2}{r} \right| kl \right\rangle - \left\langle ij \left| \frac{e^2}{r} \right| lk \right\rangle \right] \nu_{jl} c_{i\sigma}^\dagger c_{k\sigma}, \end{aligned} \quad (2.7)$$

where

$$K_{ij} = N^{-1} \sum_{\mathbf{k}} \varepsilon_{\mathbf{k}} e^{i\mathbf{k}\cdot(\mathbf{R}_i - \mathbf{R}_j)}, \quad (2.8)$$

and

$$\nu_{jl} = N^{-1} \sum_{\mathbf{k}} e^{i\mathbf{k}\cdot(\mathbf{R}_j - \mathbf{R}_l)} \quad (2.9)$$

Now comes the crucial approximation. For a narrow energy band, the Wannier functions  $\phi$  nearly coincide with atomic  $s$ -functions. For small bandwidth, these  $s$ -functions form an atomic shell whose radius is small compared with the spacing between atoms (or lattice constant). Thus, the integral  $U = \langle ii | e^2/r | ii \rangle$  should be much larger than all other integrals. This suggests the seemingly crude approximation of neglecting all other integrals. It turns out that this approximation is not so radical as it could seem at first sight since the other integrals are indeed much smaller than  $U$ . In fact, for example, for  $3d$  electrons of transition metals they are smaller by about two orders of magnitude [28].

Keeping only the terms in  $U$  in the interaction part, we obtain

$$\mathcal{H} = \sum_{i,j,\sigma} K_{ij} c_{i\sigma}^\dagger c_{j\sigma} + \frac{U}{2} \sum_{i\sigma} n_{i\sigma} n_{i,-\sigma} - U \sum_{i,\sigma} \nu_{i,i} n_{i,\sigma} \quad (2.10)$$

where  $n_{i\sigma} = c_{i\sigma}^\dagger c_{i\sigma}$ . Note that  $\nu_{i,i} = N^{-1} \sum_{\mathbf{k}} \nu_{\mathbf{k}} = n/2$ , which means that the last term is constant and may be dropped. Now, the hopping matrix  $\mathbf{K}$  can, in principle, be found by inverse Fourier transforming the dispersion relation  $\varepsilon_{\mathbf{k}}$  of the interaction free system, that we can imagine to be obtained experimentally.

For a nearly free electron gas, we have a well defined crystal wavevectors that depends on the symmetry of the lattice, which may be written as Fourier transforms

$$|\mathbf{k}\rangle \equiv \frac{1}{N} \sum_{\mathbf{r}} e^{i\mathbf{k}\cdot\mathbf{r}} |\mathbf{r}\rangle \quad (2.11)$$

Recalling the form of the hopping Hamiltonian

$$\mathcal{H}_{\text{hop}} = - \sum_{\mathbf{r}\mathbf{r}'} K(\mathbf{r} - \mathbf{r}') |\mathbf{r}'\rangle \langle \mathbf{r}| \quad (2.12)$$

we can obtain the dispersion relation.

$$\begin{aligned} -\mathcal{H}_{\text{hop}} |\mathbf{k}\rangle &= \frac{1}{\sqrt{N}} \sum_{\mathbf{r}\mathbf{r}'} K(\mathbf{r} - \mathbf{r}') e^{i\mathbf{k}\cdot\mathbf{r}'} |\mathbf{r}'\rangle \\ &= \frac{1}{\sqrt{N}} \left( \sum_{\mathbf{R}} K(\mathbf{R}) e^{i\mathbf{k}\cdot\mathbf{R}} \right) \left( \sum_{\mathbf{r}'} e^{i\mathbf{k}\cdot\mathbf{r}'} |\mathbf{r}'\rangle \right) \\ &= \varepsilon_{\mathbf{k}} |\mathbf{k}\rangle \end{aligned} \quad (2.13)$$

and here we recognize the dispersion relation as the (negative) Fourier transform of the hopping

$$\varepsilon_{\mathbf{k}} = - \sum_{\mathbf{R}} K(\mathbf{R}) e^{i\mathbf{k}\cdot\mathbf{R}} \quad (2.14)$$

This gives us an interpretation of the  $\mathbf{K}$  matrix: given the dispersion relation, and considering the solid to be well described by a tight binding model, we can easily obtain the matrix elements  $K_{ij}$ .

Let us now suppose that we have the simplest uniform nearest neighbor hopping model. Going back to equation (2.8), and recalling that the sum on  $\mathbf{k}$  is restricted to the first Brillouin zone, we obtain the usual tight binding result:  $K_{\langle ij \rangle} = -t \in \mathbb{R}$  and 0 otherwise (i.e.  $\mathbf{K}$  is a very sparse matrix that is only non-zero for  $i, j$  nearest neighbors). The Hubbard Hamiltonian is then

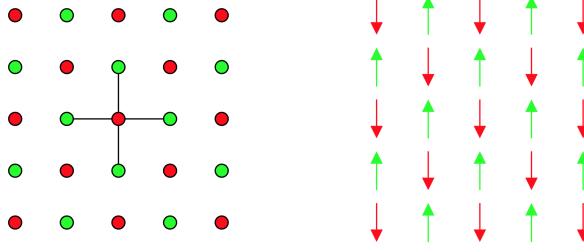

$$\mathcal{H} = -t \sum_{\langle i,j \rangle, \sigma} \left( c_{i,\sigma} c_{j,\sigma}^\dagger + c_{j,\sigma} c_{i,\sigma}^\dagger \right) + U \sum_i n_{i,\uparrow} n_{i,\downarrow} \quad (2.15)$$

### 2.2.3 Particle-hole symmetry

In this section we examine a particularly relevant and unique symmetry of the Hubbard model. The main idea is that, at half filling, the Hubbard Hamiltonian is invariant under a transformation which turns particles into holes and vice-versa. Particle-hole symmetry (PHS) allows us to relate the properties of the Hubbard Hamiltonian at different values of the parameters. Moreover, it allows us to devise a mapping between the attractive ( $U < 0$ ) and the repulsive ( $U > 0$ ) models. We will see later that this mapping is important in QMC simulations [61].

We start our discussion with the concept of a bipartite lattice. A lattice is said to be bipartite if it can be divided into two sublattices  $\mathcal{A}$  and  $\mathcal{B}$ , such that the set of neighbors of a site in sublattice  $\mathcal{A}$  belongs to sublattice  $\mathcal{B}$ . For example, the square and honeycomb lattices are bipartite, whereas the triangular lattice is not.

In a bipartite lattice, antiferromagnetic (AF) order is favored. In contrast, AF order is frustrated on the triangular and other non bipartite lattices.

**Figure 2.3:** On the left, we see that the square lattice is bipartite. The neighbors of a particular in the red sublattice all belong to the green sublattice. The picture on the right, is meant to give some intuition on why the bipartite lattice favors AF order. We represent a configuration where fermions of a given spin have as their neighbors only fermions of opposite spin (taken from [61]).

Introducing a Particle-hole transformation (PHT),

$$d_{i,\sigma}^\dagger = (-1)^i c_{i,\sigma}, \quad (2.16)$$

we exchange the role of annihilation and creation operators.

In fact, particles become holes and vice-versa:  $d_{i,\sigma}^\dagger d_{i,\sigma} = 1 - c_{i,\sigma}^\dagger c_{i,\sigma}$ , and the occupations  $n = 0, 1$  are interchanged.

Consider a bipartite lattice. Since in that case the factor  $(-1)^i$  takes on  $-1$  on one sublattice and  $1$  on the other, the kinetic part of the Hamiltonian is invariant under a PHT:

$$c_{i,\sigma}^\dagger c_{j,\sigma} + c_{j,\sigma}^\dagger c_{i,\sigma} \mapsto (-1)^{i+j} (d_{i,\sigma}^\dagger d_{j,\sigma}^\dagger + d_{j,\sigma}^\dagger d_{i,\sigma}^\dagger) = d_{j,\sigma}^\dagger d_{i,\sigma} + d_{i,\sigma}^\dagger d_{j,\sigma} \quad (2.17)$$

The PHS of the kinetic term can be incorporated into the interaction term by a shift in the chemical potential and by adding a constant to the Hamiltonian. First, note that the term

$$U(n_{i,\uparrow} - \frac{1}{2})(n_{i,\downarrow} - \frac{1}{2})$$

is unchanged under a PHT.

Expanding this term, we obtain  $U n_{i,\uparrow} n_{i,\downarrow} - \frac{U}{2} (n_{i,\uparrow} + n_{i,\downarrow}) + \frac{U}{4}$ , which indeed differs from the original interaction term by a shift in the chemical potential plus a constant. Thus, the particle-hole symmetric form of the Hamiltonian

$$\mathcal{H} = -t \sum_{\langle i,j \rangle, \sigma} (c_{i,\sigma} c_{j,\sigma}^\dagger + c_{j,\sigma}^\dagger c_{i,\sigma}) + U \sum_i (n_{i,\uparrow} - \frac{1}{2})(n_{i,\downarrow} - \frac{1}{2}) - \mu \sum_i (n_{i,\uparrow} + n_{i,\downarrow}) \quad (2.18)$$

is completely equivalent to the original Hamiltonian.

Under a PHT, the density transforms as  $\rho \mapsto 2 - \rho$ . The Hamiltonian changes only in the chemical potential term:  $\mu \mapsto -\mu$ . Thus, we have that  $\rho(\mu) = 2 - \rho(-\mu)$ , and at  $\mu = 0$ , we have half filling:  $\rho = 1$ . This reasoning is valid for any  $\beta$ ,  $t$ , or  $U$ , which implies that the phase diagram of the Hubbard model must be symmetric about half filling. Suppose you added next nearest neighbor (NNN) hoppings  $t'$ <sup>5</sup>. Then, PHS would be broken, and the phase diagram would no longer be symmetric about  $\mu = 0$ . Indeed, a modified version of the Hubbard model with NNN hoppings is often used to model cuprate

<sup>5</sup>On the square lattice, this corresponds to connecting sites across the diagonal of each square.

superconductors, and this lack of symmetry is consistent with the fact that hole- and electron-doped cuprates have different properties.

## 2.3 Mott insulators

Band theory was found to be flawed soon after it was introduced. The picture it proposes is simple and generally works pretty well. It is based on considering the electrons to be independently moving under the constant background potential created by the ions. The solutions of the Schrödinger for free electrons in a periodic potential  $U(\mathbf{r})$ , such that  $U(\mathbf{r}) = U(\mathbf{r} + \mathbf{R})$ ,

$$\left[ -\frac{1}{2m} \nabla^2 + U(\mathbf{r}) \right] \psi(\mathbf{r}) = \varepsilon \psi(\mathbf{r}) \quad (2.19)$$

are given by Bloch's theorem:  $\psi_{\mathbf{k}}(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}} u_{\mathbf{k}}(\mathbf{r})$ . Note that we made  $\hbar = 1$ . Replacing this wave function in equation (2.19), we obtain a differential equation for  $u_{\mathbf{k}}(\mathbf{r})$ , which has in general an infinite number of solutions. We label them with an index  $n$ , which we call the band index. To each solution there corresponds a function  $\varepsilon_{n\mathbf{k}}$ . The set of these functions is known as the band structure. Since electrons are taken to be independent in band theory, the  $N$ -electron eigenstates are obtained by placing an electron in each quantum state. Each state is labelled by its energy  $\varepsilon_{n\mathbf{k}\sigma}$ . Since our model Hamiltonian does not couple spins (via an electron interaction, for example) and assuming there is no external magnetic field and that the system has an inversion center, we have  $\varepsilon_{n\mathbf{k}\uparrow} = \varepsilon_{n\mathbf{k}\downarrow}$ . In general there might be energies for which there is no corresponding  $\varepsilon_{n\mathbf{k}\sigma}$ . These form intervals called forbidden bands<sup>6</sup>. Thus, the ground state of our model may be obtained by filling the energy levels starting from the lowest energy state. Two cases are particularly relevant:

- Every band is either fully occupied or empty. The first excited state differs from the ground state by  $\Delta$ , the separation between the last fully occupied band and the first empty band. It is then impossible to induce the motion of the electrons by applying an arbitrarily small voltage. This is what it means to be an *insulator*. Since there  $2N$  states per band, this is not possible unless the number of electrons per unit cell is an even integer.
- One or more of the bands are partially filled. The energy of occupied state of higher energy is named the Fermi energy  $\varepsilon_F$ . In this case, the separation between the ground state and the first excited state tends to 0 in the thermodynamic limit,  $N \rightarrow \infty$ . The system may then respond to infinitesimal excitations, which is the definition of a metal.

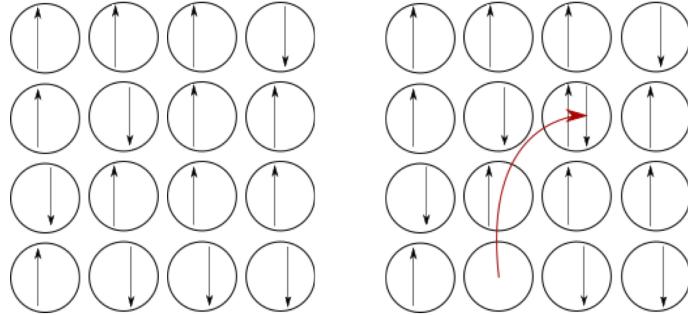

Band theory made it possible to predict whether a solid would be a metal or an insulator. However, its success rests crucially on the independent electron approximation. Thus, it is not surprising that for compounds with strongly correlated electrons the theory might fail [62]. The Coulomb interaction is in general non negligible, and the effects it leads to are not captured by a mean field approach. One must resort to many-body theory. An example of a many-body effect that band theory doesn't capture is superconductivity. However, this does not deem band theory useless. In fact, the superconducting

---

<sup>6</sup>We disregard surface states that may have energies that fall in the forbidden bands.

phase arises due to an instability of a state that is itself well described by band theory [63]. A far greater failure of band theory is that predicts certain compounds with an odd number of electrons per unit cell, such as NiO and La<sub>2</sub>CuO<sub>4</sub>, to be metals, while in fact they turn out to be (Mott) insulators. Mott devised a simple argument to justify this failure. It is based on considering the elementary electronic excitations of a solid composed by hydrogen atoms as a function of the distance between atoms.

Consider a hypothetical solid consisting of a square lattice with hydrogen atoms on its points. Each unit cell has one hydrogen atom, and consequently one electron. Band theory would predict such a solid to be a metal. However, if the lattice parameter  $a$  is large enough, the solid cannot remain a metal. There must be some value of the lattice parameter  $a = a_c$  for which the system becomes an insulator. When current flows through a sample of this solid, electrons hop consecutively, reaching positions that can be quite far on the lattice. For a metal, this process occurs even when exciting the system with an infinitesimal amount of energy. How much energy do we need to provide for this process to occur?

**Figure 2.4:** On the right, a configuration on the square lattice with a hole and a doubly occupied site obtained by delocalization of the spin down electron on the left.

If  $a$  is large, we have essentially one electron per site at the start. When an electron is displaced, we end up with a hole and a doubly occupied site. The potential energy of such a state is

$$E_{H^-} + E_{H^+} - 2E_H \quad (2.20)$$

Due to the Coulomb repulsion between the two electrons in  $H^-$ , this quantity is strictly positive. Call it  $U > 0$ . On the other hand, the system also has kinetic energy: both the hole and the doubly occupied site can delocalize. Let  $W$  be the bandwidth corresponding to the delocalization of an electron on the lattice. Both the hole and the doubly occupied will stay at the bottom of the band and gain an energy  $W/2$  (assuming that this delocalization is of the same order of magnitude). The dominant transfer integral  $-t$  is between nearest neighbors. The dispersion relation then reads

$$\varepsilon_{\mathbf{k}} = -2t(\cos k_x + \cos k_y) \quad (2.21)$$

The bandwidth is then  $W = 8t$ . The energy of a configuration with a hole and a doubly occupied site is

$$\Delta_c = U - W, \quad (2.22)$$

where  $U$  is practically independent of the lattice parameter  $a$ . The bandwidth  $W$ , however, depends strongly on  $a$ . When  $a \gg a_0$ , where  $a_0$  is the Bohr radius, the transfer integral is exponentially small, because only the exponential tails of the wave functions are relevant. In this limit,  $\Delta_c \approx U$  is a large, positive number, and the system is an insulator. This type of insulator is called a Mott insulator, and  $\Delta_c$  is called the charge gap. As  $a$  decreases,  $t$  increases, and there must be a critical value  $a_c \sim a_0$ , for which  $U = W$ . Below this value, the computation of  $\Delta_c$  is not valid anymore because the gap cannot be negative. Thus, there must be a metal-insulator transition. It is possible to see this transition if we apply enough pressure to a Mott insulator so as to decrease  $a$  and increase  $t$ . A transition of this type was first seen in the 1970's for  $V_2O_3$ <sup>7</sup>. There is a fundamental difference between a band insulator and a Mott insulator. While we must pay an energy  $\Delta_c$  to make a charge excitation, this is not the cost of a spin excitation: we can flip the spin of an electron without creating a doubly occupied site. The fluctuations of both charge and spin due to the electron interactions may then lead to magnetic behavior characteristic of this type of systems.

## 2.4 Exact solutions for simple cases

In PHS form, the Hubbard Hamiltonian may then be written as a sum of kinetic, chemical and potential energy terms, respectively:

$$\mathcal{H} = \mathcal{H}_K + \mathcal{H}_\mu + \mathcal{H}_V, \quad (2.23)$$

defined as

$$\begin{aligned} \mathcal{H}_K &= -t \sum_{\langle i,j \rangle, \sigma} (c_{i,\sigma} c_{j,\sigma}^\dagger + c_{j,\sigma}^\dagger c_{i,\sigma}) \\ \mathcal{H}_\mu &= -\mu \sum_i (n_{i,\uparrow} + n_{i,\downarrow}) \\ \mathcal{H}_V &= U \sum_i (n_{i,\uparrow} - \frac{1}{2})(n_{i,\downarrow} - \frac{1}{2}) \end{aligned}, \quad (2.24)$$

where:

- $i$  and  $j$  label sites on the lattice.
- $c_{i,\sigma}^{(\dagger)}$  is an operator that annihilates (creates) an electron with spin  $\sigma$  on site  $i$ .
- $n_{i,\sigma}$  is the number operator counting the number of electrons of spin  $\sigma$  on site  $i$  (either 0 or 1).
- $t$  is the hopping parameter related to the kinetic energy of the electrons. It is determined by the overlap of the atomic wave functions on neighboring sites  $\langle i, j \rangle$ .

---

<sup>7</sup>Of course, the transition is not so easy to describe. However, this simple argument provides an intuitive picture.

- $U$  is the repulsive Coulomb interaction between electrons on the same lattice site. Whenever a site  $i$  has two electrons, there is a local repulsion between them corresponding to an energy cost  $Un_{i\uparrow}n_{i\downarrow}$ . The constant  $1/2$  terms serve to recast the Hamiltonian in particle-hole symmetric form.
- $\mu$  is the chemical potential controlling the electron number (or density).

A given physical observable of interest  $\mathcal{O}$ , such as the spin-spin correlation, or the magnetic susceptibility may be computed formally by

$$\langle \mathcal{O} \rangle = \text{Tr}(\mathcal{O}\mathcal{P}) \quad (2.25)$$

where

$$\mathcal{P} \equiv \frac{1}{Z} e^{-\beta \mathcal{H}}, \text{ with } Z = \text{Tr}(e^{-\beta \mathcal{H}}) \quad (2.26)$$

The trace is taken over the Hilbert space corresponding to all possible configurations of the lattice occupation. Defining an orthonormal basis of this Hilbert space  $\{|\psi_\alpha\rangle | \alpha = 1, \dots, D\}$ , where  $D$  is the dimension of the Hilbert space, the partition function reads

$$\text{Tr}(e^{-\beta \mathcal{H}}) = \sum_{\alpha} \langle \psi_{\alpha} | e^{-\beta \mathcal{H}} | \psi_{\alpha} \rangle \quad (2.27)$$

There are four possible states at each site in the Hubbard model:  $| \rangle$ ,  $|\uparrow\rangle$ ,  $|\downarrow\rangle$ ,  $|\uparrow\downarrow\rangle$ , corresponding, respectively, to no electron, a spin up or spin down electron, and two electrons of opposite spin occupying the site. The potential energy operator acts as follows

$$U(n_{i\uparrow} - \frac{1}{2})(n_{i\downarrow} - \frac{1}{2}) \begin{cases} | \rangle = \frac{U}{4} | \rangle \\ |\uparrow\rangle = -\frac{U}{4} |\uparrow\rangle \\ |\downarrow\rangle = -\frac{U}{4} |\downarrow\rangle \\ |\uparrow\downarrow\rangle = \frac{U}{4} |\uparrow\downarrow\rangle \end{cases} \quad (2.28)$$

Singly occupied states ( $|\uparrow\rangle$ ,  $|\downarrow\rangle$ ) have lower energy and are thus more likely to occur. They correspond to nonzero magnetization  $m = n_{\uparrow} - n_{\downarrow}$ , which is favored by the Hubbard interaction  $U$ . A relevant question is whether or not the spins order in space when  $t \neq 0$  and to what extent.

Let us now establish our notations for second quantized operators to introduce a different representation of electronic states on the lattice. The fermionic annihilation and creation operators anti-commute.

$$\{c_{j\sigma}, c_{l\sigma'}^\dagger\} = \delta_{jl} \delta_{\sigma\sigma'} \quad (2.29)$$

The  $c$ -operator algebra is further defined by the vanishing of all other anticommutators.

$$\{c_{j\sigma}^{(\dagger)}, c_{l\sigma'}^{(\dagger)}\} = 0 \quad (2.30)$$

Note that taking  $l = j$  and  $\sigma = \sigma'$  in equation (2.30) for the  $c^\dagger$ -operators, we recover Pauli's exclusion principle since  $(c_{j\sigma}^\dagger)^2 = 0$ . If we omit the site  $i$  and spin  $\sigma$  indices, a convenient way of specifying states on the lattice is

$$\begin{aligned} |0\rangle &: \text{unoccupied state - no electron} \\ |1\rangle &: \text{occupied state - one electron} \end{aligned} \quad (2.31)$$

so that a generic state may be written as a product of the states above  $\otimes_{i=1}^N \otimes_{\sigma=\pm 1/2} |n\rangle_{i,\sigma}$  at each site for each spin state, where  $n = 0, 1$ . For example, one such state is

$$|0\rangle_{1,1/2} |1\rangle_{1,-1/2} |0\rangle_{2,1/2} |0\rangle_{2,-1/2} \dots |0\rangle_{N,1/2} |1\rangle_{N,-1/2}, \quad (2.32)$$

where  $N$  is the number of sites on the lattice.

The creation and annihilation operators act as follows

$$c|0\rangle = 0 \quad c^\dagger|0\rangle = |1\rangle \quad c|1\rangle = |0\rangle \quad c^\dagger|1\rangle = 0 \quad (2.33)$$

Thus, the eigenstates of the number operator are  $|0\rangle, |1\rangle$ :

$$n|0\rangle = 0 \quad n|1\rangle = |1\rangle \quad (2.34)$$

Moreover, the operator  $c_i^\dagger c_{i+1}^\dagger$ , corresponding to the hopping from site  $i+1$  to  $i$ , i.e. to the kinetic energy of the electrons on neighboring sites, acts as follows (ignoring spin):

$$c_i^\dagger c_{i+1}^\dagger \begin{cases} |00\rangle = 0 \\ |10\rangle = 0 \\ |01\rangle = |10\rangle \\ |11\rangle = c_i^\dagger |10\rangle = 0 \end{cases} \quad (2.35)$$

The operator annihilates the particle at  $i+1$  and creates it back at  $i$ , i.e. the electron hops from  $i+1$  to  $i$ .

#### 2.4.1 The purely atomic $\frac{t}{U} = 0$ limit

When  $t = 0$ , the site index may be omitted since the Hamiltonian is a sum of operators solely at site  $i$ . Hence, we have  $[\mathcal{H}, n_{i,\sigma}] = 0 \forall i$ , and the eigenstates of  $\mathcal{H}$  are also eigenstates of all number operators at the different sites in the lattice. Thus, in the single site limit, we obtain

$$\mathcal{H} = U(n_\uparrow - \frac{1}{2})(n_\downarrow - \frac{1}{2}) - \mu(n_\uparrow + n_\downarrow) \quad (2.36)$$

which acts as follows (using the eigenstates of  $n_\sigma$ )

$$\mathcal{H} \begin{cases} | \rangle = \frac{U}{4} \\ |\uparrow\rangle = \left( \frac{U}{4} - (\mu + \frac{U}{2}) \right) |\uparrow\rangle \\ |\downarrow\rangle = \left( \frac{U}{4} - (\mu + \frac{U}{2}) \right) |\downarrow\rangle \\ |\uparrow\downarrow\rangle = \left( \frac{U}{4} - 2\mu \right) |\uparrow\downarrow\rangle \end{cases} \quad (2.37)$$

Thus, the Hamiltonian is diagonal in the basis  $\{|\psi_\alpha\rangle\} = |\rangle, |\uparrow\rangle, |\downarrow\rangle, |\uparrow\downarrow\rangle$ :

$$\begin{aligned} [\mathcal{H}_{\rho\gamma}] &= \left[ \langle \psi_\rho | \mathcal{H} | \psi_\gamma \rangle \right] \\ &= \text{diag}\left( \frac{U}{4}, \frac{U}{4} - (\mu + \frac{U}{2}), \frac{U}{4} - (\mu + \frac{U}{2}), \frac{U}{4} - 2\mu \right), \end{aligned} \quad (2.38)$$

which means that  $e^{-\beta\mathcal{H}}$  is also diagonal:

$$e^{-\beta\mathcal{H}} = e^{-\beta U/4} \text{diag}\left( 1, e^{\beta(\mu+\frac{U}{2})}, e^{\beta(\mu+\frac{U}{2})}, e^{2\beta\mu} \right) \quad (2.39)$$

and this is one of the rare situations in which it is possible to explicitly write down a closed form for the partition function.

$$\begin{aligned} Z &= \text{Tr}(e^{-\beta\mathcal{H}}) = \sum_{\alpha} \langle \psi_\alpha | e^{-\beta\mathcal{H}} | \psi_\alpha \rangle \\ &= e^{-\beta U/4} \left( 1 + 2e^{\beta(\mu+\frac{U}{2})} + e^{2\beta\mu} \right) \end{aligned} \quad (2.40)$$

Moreover, some of the observables that were mentioned before are explicitly computable. This is because due to the diagonal form of  $\mathcal{H}$ , the expressions defining these observables greatly simplify.

$$\begin{aligned} \mathcal{H}e^{-\beta\mathcal{H}} &\mapsto e^{-\beta U/4} \text{diag}\left( \frac{U}{4}, (-\mu - \frac{U}{4})e^{\beta(\mu+\frac{U}{2})}, (-\mu - \frac{U}{4})e^{\beta(\mu+\frac{U}{2})}, (\frac{U}{4} - 2\mu)e^{2\beta\mu} \right) \\ n_{\uparrow}e^{-\beta\mathcal{H}} &\mapsto e^{-\beta U/4} \text{diag}\left( 0, e^{\beta(\mu+\frac{U}{2})}, 0, e^{2\beta\mu} \right) \\ n_{\downarrow}e^{-\beta\mathcal{H}} &\mapsto e^{-\beta U/4} \text{diag}\left( 0, 0, e^{\beta(\mu+\frac{U}{2})}, e^{2\beta\mu} \right) \\ n_{\uparrow}n_{\downarrow}e^{-\beta\mathcal{H}} &\mapsto e^{-\beta U/4} \text{diag}\left( 0, 0, 0, e^{2\beta\mu} \right) \end{aligned} \quad (2.41)$$

From these we can compute some traces which we shall find useful to obtain averages of various observables.

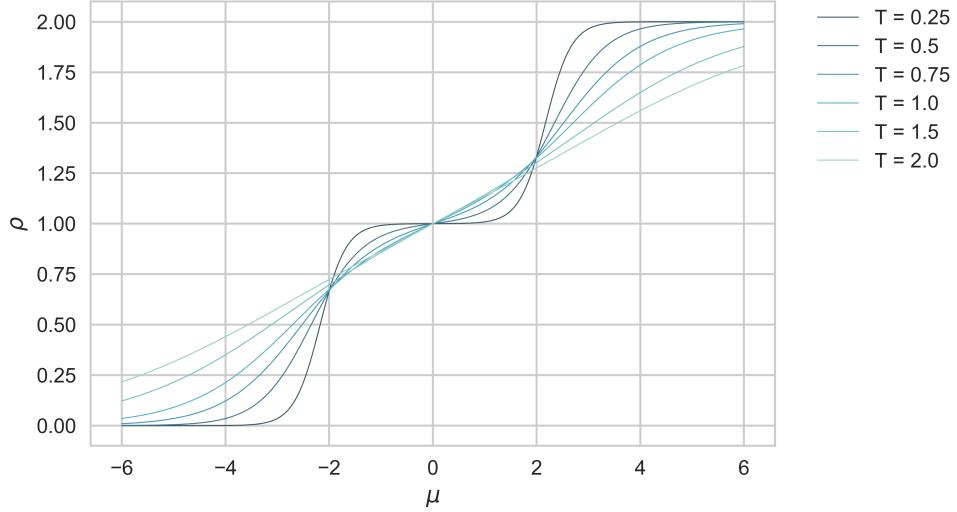

$$\begin{aligned}
\text{Tr} \left( \mathcal{H} e^{-\beta \mathcal{H}} \right) &= e^{-\beta U/4} \left( \frac{U}{4} + 2(-\mu - \frac{U}{4})e^{\beta(\mu + \frac{U}{2})} + (\frac{U}{4} - 2\mu)e^{2\beta\mu} \right) \\
\text{Tr} \left( (n_\uparrow + n_\downarrow) e^{-\beta \mathcal{H}} \right) &= e^{-\beta U/4} \left( 2(-\mu - \frac{U}{4})e^{\beta(\mu + \frac{U}{2})} + (\frac{U}{4} - 2\mu)e^{2\beta\mu} \right) \\
\text{Tr} \left( n_\uparrow n_\downarrow \right) &= e^{-\beta U/4} e^{2\beta\mu}
\end{aligned} \tag{2.42}$$

The bottom line is that we are able to obtain *exact* expressions for

1. the one-site density  $\rho = \langle n_\uparrow \rangle + \langle n_\downarrow \rangle$ , measuring the average occupation of each site.

$$\begin{aligned}
\rho &= \frac{\text{Tr}[(n_\uparrow + n_\downarrow) e^{-\beta \mathcal{H}}]}{Z} \\
&= \frac{2e^{\beta(\frac{U}{2} + \mu)} + 2e^{2\beta\mu}}{1 + 2e^{\beta(\mu + \frac{U}{2})} + e^{2\beta\mu}}
\end{aligned} \tag{2.43}$$

Note that when there is no chemical potential  $\mu = 0$ , we have  $\rho = 1$  for any  $U$ , or  $\beta$ . This corresponds to half filling: the density of electrons is half its maximum possible value.

**Figure 2.5**

2. the one-site energy  $E = \langle \mathcal{H} \rangle$ .

$$\begin{aligned}
E &= \frac{\text{Tr}(\mathcal{H} e^{-\beta \mathcal{H}})}{Z} \\
&= \frac{\frac{U}{4} + 2(-\mu - \frac{U}{4})e^{\beta(\frac{U}{2} + \mu)} + (\frac{U}{4} - 2\mu)e^{2\beta\mu}}{1 + 2e^{\beta(\frac{U}{2} + \mu)} + e^{2\beta\mu}} \\
&= \frac{\frac{U}{4}(1 + 2e^{\beta(\frac{U}{2} + \mu)} + e^{2\beta\mu}) + 2(-\mu - \frac{U}{4})e^{\beta(\frac{U}{2} + \mu)} - 2\mu e^{2\beta\mu} - 2\frac{U}{4}e^{\beta(\frac{U}{2} + \mu)}}{1 + 2e^{\beta(\frac{U}{2} + \mu)} + e^{2\beta\mu}} \\
&= \frac{U}{4} - \frac{(2\mu - U)e^{\beta(\frac{U}{2} + \mu)} + 2\mu e^{2\beta\mu}}{1 + 2e^{\beta(\frac{U}{2} + \mu)} + e^{2\beta\mu}}
\end{aligned} \tag{2.44}$$

which at half filling becomes

$$E = \frac{U}{4} - \frac{U}{2(1 + e^{-\beta U/2})} \quad (2.45)$$

3. the double occupancy  $\langle n_{\uparrow}n_{\downarrow} \rangle$ .

$$\langle n_{\uparrow}n_{\downarrow} \rangle = \frac{\text{Tr}[n_{\uparrow}n_{\downarrow}]}{Z} = \frac{e^{2\beta\mu}}{1 + 2e^{\beta(\frac{U}{2} + \mu)} + e^{2\beta\mu}} \quad (2.46)$$

which, at half filling, simplifies to

$$\langle n_{\uparrow}n_{\downarrow} \rangle = \frac{1}{2(1 + e^{\beta U/2})} \quad (2.47)$$

Note that as either  $U$  or  $\beta$  increase the double occupancy tends to zero.

#### 2.4.2 The non-interacting $\frac{t}{U} \rightarrow \infty$ limit

In the  $\frac{t}{U} \rightarrow \infty$  limit, the spin spaces become independent, and they may be considered separately. Thus, we omit the spin indices of the operators in the Hamiltonian:

$$\mathcal{H} = -t \sum_{\langle i,j \rangle} (c_i^\dagger c_j + c_j^\dagger c_i) - \mu \sum_i n_i \quad (2.48)$$

which may be recast as a bilinear form

$$\mathcal{H} = \mathbf{c}^\dagger (-t\mathbf{K} - \mu\mathbf{I})\mathbf{c}, \quad (2.49)$$

where

$$\mathbf{c} = \begin{bmatrix} c_1 & c_2 & \dots & c_N \end{bmatrix}^T \quad \mathbf{c}^\dagger = \begin{bmatrix} c_1^\dagger & c_2^\dagger & \dots & c_N^\dagger \end{bmatrix} \quad (2.50)$$

and  $\mathbf{I}$  is the identity matrix. We also defined a matrix of zeros and ones specifying the hopping geometry,  $\mathbf{K}$ . When writing down  $\mathbf{K}$ , we must specify the boundary conditions. periodic boundary conditions (PBCs) preserve a system's translational invariance and are advantageous because they reduce finite size effects. An example of a quantity which is measured more accurately is energy. In the thermodynamic limit,  $N \rightarrow \infty$ , the measured energy differs from the actual value by a correction of order  $\mathcal{O}(\frac{1}{N^2})$  with PBCs, while for open boundary conditions (OBCs), the correction is of order  $\mathcal{O}(\frac{1}{N})$  [64]. Additionally, PBCs have the property of giving site independent observables. For example, the electron density per site does not vary with PBCs, but it varies with the distance to the edges of the lattice when we use OBCs.

Consider a rectangular two-dimensional lattice with  $N_x \times N_y$  sites. Then, we have  $\dim(\mathbf{K}) = N_x N_y \times N_x N_y$ , and

$$\mathbf{K} = \mathbf{I}_y \otimes \mathbf{K}_x + \mathbf{I}_x \otimes \mathbf{K}_y, \quad (2.51)$$

where  $\mathbf{I}_{x,y}$  are identity matrices of dimension  $N_{x,y}$ , respectively, and  $\mathbf{K}_{x,y}$  are the hopping matrices in

the  $x$  and  $y$ -directions respectively.

For lattices in 1D or 2D, it is possible to find an exact eigendecomposition

$$\mathbf{K} = \mathbf{F}^T \boldsymbol{\Lambda} \mathbf{F} \quad \text{with} \quad \mathbf{F}^T \mathbf{F} = \mathbf{I}, \quad (2.52)$$

where  $\boldsymbol{\Lambda} = \text{diag}(\lambda_k)_{k=1}^{N_x N_y}$  is a diagonal matrix of eigenvalues of  $\mathbf{K}$ . The Hamiltonian is diagonalized:

$$\mathcal{H} = \tilde{\mathbf{c}}^\dagger (-t\mathbf{K} - \mu \mathbf{I}) \tilde{\mathbf{c}} = \sum_k \varepsilon_k \tilde{n}_k, \quad (2.53)$$

where  $\tilde{\mathbf{c}} = \mathbf{F} \mathbf{c}$  and  $\tilde{\mathbf{c}}^\dagger = (\mathbf{F} \mathbf{c})^\dagger$ , and

$$\varepsilon_k = -t\lambda_k - \mu \quad \tilde{n}_k = \tilde{c}_k^\dagger \tilde{c}_k \quad (2.54)$$

The  $\tilde{c}$ -operators are equally valid electron creation/annihilation operators, obeying the same anticommutation relations as the original operators  $c_i$ . While the original operators create/annihilate particles at specific (spatial) sites, the new ones create/annihilate particles with momentum  $k$ . Both sets of operators describe the same physics, however the interaction term in the Hubbard model is fairly complex to write in momentum space so it is not possible to apply this procedure to diagonalize it.

Now, it turns out that it is easy to evaluate the partition function for quadratic Hamiltonians. If  $\mathcal{H} = \mathbf{c}^\dagger \mathbf{H} \mathbf{c}$ , where  $\mathbf{H}$  is a  $N \times N$  Hermitian matrix, then we have that

$$\text{Tr}[e^{-\beta \mathcal{H}}] = \prod_{i=1}^N (1 + e^{-\beta \lambda_{k_i}}), \quad (2.55)$$

where  $\lambda_{k_i}$  are the eigenvalues of  $\mathbf{H}$ .

We present a proof of this result in appendix B.

Thus, this result suggests that if we are able to devise some approximation to transform the quartic term of the interacting Hubbard model in a quadratic form, then we can solve it.

To complete the solution of the non-interacting case we apply the result of equation (2.55) to compute the partition function corresponding to the quadratic Hamiltonian defined in equation (2.53):

$$Z = \prod_k (1 + e^{-\beta \varepsilon_k}) \quad (2.56)$$

Now that we have found a closed form solution for  $Z$ , it is again possible to find closed form expressions for observables of interest as well, namely:

1. the density, or average occupation of each site,  $\rho$ .

$$\rho = \langle n \rangle = \langle \tilde{n} \rangle = \frac{1}{N} \sum_{k=1}^N \langle \tilde{n}_k \rangle = \frac{1}{N} \sum_{k=1}^N \frac{1}{1 + e^{\beta \varepsilon_k}} \quad (2.57)$$

2. the energy  $E = \langle \mathcal{H} \rangle$ .

$$E = \frac{1}{N} \sum_k \frac{\varepsilon_k}{1 + e^{\beta \varepsilon_k}} \quad (2.58)$$

3. the equal-time Green's function, which plays a key role in computing other quantities, such as correlation functions.

$$G_{lj} = \langle c_l c_j^\dagger \rangle = \frac{1}{N} \sum_k e^{ik \cdot (l-j)} (1 - f_k), \quad (2.59)$$

where  $f_k = (1 + e^{\beta(\varepsilon_k - \mu)})^{-1}$  is the Fermi-Dirac distribution (of course, here we consider half filling:  $\mu = 0$ ). Note that the Green function, like the Hamiltonian, is translationally invariant:  $G_{lj} = G_{l-j}$ . If we use PBCs, no site is singled out, they are all equivalent and this behavior of the Green's function should become apparent.

## 2.5 Effective Heisenberg Hamiltonian

Mott insulators allow low energy magnetic excitations (spin flips). The insulating phase corresponds to a configuration where each atom has an odd number of electrons, let's say one. This electron may have its spin up or down. In the purely atomic limit  $\frac{t}{U} \rightarrow 0$ , the atoms are infinitely far, and the excitation spectrum is very simple. The ground state is highly degenerate: every configuration with one electron per site is a ground state. As a matter of fact, the ground state is  $2^N$ -fold degenerate. The first excited state corresponds to configurations with a hole and a doubly occupied site. Let us set the energy of the ground state to zero in our conventions. The energy of these configurations is then  $U$ , and there are  $N(N-1)2^{N-2}$  of them. This process of generating higher energy excitations may be continued.

When the atoms are brought together, the first effect is the lifting of the degeneracy of the ground state, i.e. the splitting of the subspace of energy  $E = 0$  in more subspaces. The effective hamiltonian describing the lifting of the degeneracy of the lowest energy band is obtained by applying degenerate perturbation theory [62] to the kinetic term of the Hubbard Hamiltonian<sup>8</sup>

$$\mathcal{H}_0 = -t \sum_{\langle i,j \rangle, \sigma} (c_{i\sigma}^\dagger c_{j\sigma} + c_{j\sigma}^\dagger c_{i\sigma}) \quad (2.60)$$

### 2.5.1 Two-site calculation

The effect of the hopping term is best understood in a minimal two-site example. There are four one-particle quantum states, represented by the action of the operators  $c_{1,\uparrow}^\dagger, c_{1,\downarrow}^\dagger, c_{2,\uparrow}^\dagger, c_{2,\downarrow}^\dagger$  on the vacuum state. There are six two-particle states in the Fock space  $|n_{1\uparrow} n_{1\downarrow} n_{2\uparrow} n_{2\downarrow}\rangle$ :

---

<sup>8</sup>An alternative method would be to use a canonical transformation technique.

$$\begin{aligned}
|1\rangle &\equiv |1, 0, 1, 0\rangle = c_{1\uparrow}^\dagger c_{2\uparrow}^\dagger |0\rangle \\
|2\rangle &\equiv |0, 1, 0, 1\rangle = c_{1\downarrow}^\dagger c_{2\downarrow}^\dagger |0\rangle \\
|3\rangle &\equiv |1, 0, 0, 1\rangle = c_{1\uparrow}^\dagger c_{2\downarrow}^\dagger |0\rangle \\
|4\rangle &\equiv |0, 1, 1, 0\rangle = c_{1\downarrow}^\dagger c_{2\uparrow}^\dagger |0\rangle \\
|5\rangle &\equiv |1, 1, 0, 0\rangle = c_{1\uparrow}^\dagger c_{1\downarrow}^\dagger |0\rangle \\
|6\rangle &\equiv |0, 0, 1, 1\rangle = c_{2\uparrow}^\dagger c_{2\downarrow}^\dagger |0\rangle
\end{aligned} \tag{2.61}$$

The two-site Hamiltonian

$$\begin{aligned}
\mathcal{H}_2 = -t & \left( c_{1\uparrow}^\dagger c_{2\uparrow} + c_{2\uparrow}^\dagger c_{1\uparrow} + c_{1\downarrow}^\dagger c_{2\downarrow} + c_{2\downarrow}^\dagger c_{1\downarrow} \right) \\
& + U(n_{1\uparrow} n_{1\downarrow} + n_{2\uparrow} n_{2\downarrow})
\end{aligned} \tag{2.62}$$

acts on the states of the Fock space as follows

$$\begin{aligned}
\mathcal{H}_2 |1\rangle &= 0 \\
\mathcal{H}_2 |2\rangle &= 0 \\
\mathcal{H}_2 |3\rangle &= -t(c_{2\uparrow}^\dagger c_{1\uparrow} + c_{1\downarrow}^\dagger c_{2\downarrow}) c_{1\uparrow}^\dagger c_{2\downarrow}^\dagger |0\rangle = -t(|5\rangle + |6\rangle) \\
\mathcal{H}_2 |4\rangle &= -t(c_{1\uparrow}^\dagger c_{2\uparrow} + c_{2\downarrow}^\dagger c_{1\downarrow}) c_{1\downarrow}^\dagger c_{2\uparrow}^\dagger |0\rangle = t(|5\rangle + |6\rangle) \\
\mathcal{H}_2 |5\rangle &= \left[ -t(c_{2\uparrow}^\dagger c_{1\uparrow} + c_{2\downarrow}^\dagger c_{1\downarrow}) + Un_{1\uparrow} n_{1\downarrow} \right] c_{1\uparrow}^\dagger c_{1\downarrow}^\dagger |0\rangle \\
&= U|5\rangle - t(|3\rangle - |4\rangle) \\
\mathcal{H}_2 |6\rangle &= \left[ -t(c_{1\uparrow}^\dagger c_{2\uparrow} + c_{1\downarrow}^\dagger c_{2\downarrow}) + Un_{2\uparrow} n_{2\downarrow} \right] c_{2\uparrow}^\dagger c_{2\downarrow}^\dagger |0\rangle \\
&= U|6\rangle - t(|3\rangle - |4\rangle)
\end{aligned} \tag{2.63}$$

When we act on the first two states we obtain 0 because every term of the Hamiltonian gives a term  $(c^\dagger)^2$ , which is 0 due to Pauli's exclusion principle. The minus signs that appear on the hopping terms stem from the fermion anticommutation relations.

Let us now diagonalize the Hamiltonian the subspace spanned by  $\{|3\rangle, |4\rangle, |5\rangle, |6\rangle\}$ . If we add states  $|3\rangle$  and  $|4\rangle$ , we get 0 when acting with the Hamiltonian.

$$\mathcal{H}_2(|3\rangle + |4\rangle) = 0 \tag{2.64}$$

On the other hand, if we subtract  $|5\rangle$  and  $|6\rangle$ , we obtain

$$\mathcal{H}_2(|5\rangle - |6\rangle) = U(|5\rangle - |6\rangle) \tag{2.65}$$

We have found two more eigenvalues (the first two were trivially found to be zero). The others are found by subtracting  $|3\rangle$  and  $|4\rangle$  and adding  $|5\rangle$  and  $|6\rangle$ .

$$\begin{aligned}\mathcal{H}_2(|3\rangle + |4\rangle) &= -2t(|5\rangle + |6\rangle) \\ \mathcal{H}_2(|5\rangle - |6\rangle) &= -2t(|3\rangle - |4\rangle) + U(|5\rangle + |6\rangle)\end{aligned}\tag{2.66}$$

The characteristic equation allowing us to find the rest of the eigenvalues in the rotated subspace spanned by  $\{|3\rangle \pm |4\rangle, |5\rangle \pm |6\rangle\}$  is

$$\begin{aligned}E(E - U) - 4t^2 &= 0 \\ \iff E_{\pm} &= \frac{U \pm \sqrt{U^2 + 16t^2}}{2}\end{aligned}\tag{2.67}$$

Taylor expanding the square root up to second order, we obtain

$$E_- = -\frac{4t^2}{U} \quad E_+ = U + \frac{4t^2}{U}\tag{2.68}$$

Thus, we have obtained the complete energy spectrum. The ground state is a non-degenerate state of energy  $-\frac{4t^2}{U}$ , while the first excited state is a 3-fold degenerate state with energy 0. The two other excited states have energies of the order of  $U$ , the first one being exactly  $U$  and the second  $U + \frac{4t^2}{U}$ .

There are four states for which the energy would be 0 if the hopping term vanished, corresponding to the four states with one electron per site. The effect of the hopping term is to lift the degeneracy by splitting the 4-fold degenerate zero energy state into a singlet of energy  $-\frac{4t^2}{U}$  and a triplet of energy 0. This is what we obtain by minimizing a Heisenberg Hamiltonian of the form

$$\mathcal{H} = \frac{4t^2}{U} \left( \mathbf{S}_1 \cdot \mathbf{S}_2 - \frac{1}{4} \right)\tag{2.69}$$

for two spins- $\frac{1}{2}$ .

It turns out that this result is yet more general. For an arbitrary number of sites, this is the form of the effective Hamiltonian at second order.

### 2.5.2 Degenerate perturbation theory

To first order in  $\mathcal{H}$ , the matrix elements of its effective Hamiltonian coincide in the ground state subspace (by definition).

$$\langle m | \mathcal{H}_{\text{eff}} | n \rangle = \langle m | \mathcal{H}_0 | n \rangle,\tag{2.70}$$

where  $|m\rangle$ , and  $|n\rangle$  belong to the ground state subspace. Since we are considering the system to be at half filling in our calculations,  $|m\rangle$ , and  $|n\rangle$  must have one electron per site. The hopping Hamiltonian  $\mathcal{H}_0$  makes an electron hop, leaving its previous site empty, and the site it hops to doubly occupied. This implies that all the matrix elements in the previous equation must be 0.

To second order, the matrix elements of the effective Hamiltonian are

$$\begin{aligned}\langle m|\mathcal{H}_{\text{eff}}|n\rangle &= \sum_{|k\rangle} \frac{\langle m|\mathcal{H}_0|k\rangle \langle k|\mathcal{H}_0|n\rangle}{E_0 - E_k} \\ &= -\frac{1}{U} \sum_{|k\rangle} \langle m|\mathcal{H}_0|k\rangle \langle k|\mathcal{H}_0|n\rangle,\end{aligned}\tag{2.71}$$

where  $|k\rangle$  are the states that are not in the ground state subspace. In the second equality we simply noted that  $\mathcal{H}_0$  creates a doubly occupied site. The energy cost of creating a doubly occupied site is  $U$ .

The identity operator in the in the subspace of states with one doubly occupied site

$$\sum_{|k\rangle} |k\rangle \langle k|$$

may be written in a more convenient form in another representation:

$$\sum_j n_{j,\sigma} n_{j,-\sigma}$$

so that the effective Hamiltonian becomes

$$\mathcal{H}_{\text{eff}} = -\mathcal{H}_0 \frac{\sum_j n_{j,\sigma} n_{j,-\sigma}}{U} \mathcal{H}_0\tag{2.72}$$

For each element  $j$  of the sum, only terms of type

$$\sum_{i(j)} c_{j\sigma}^\dagger c_{i\sigma}$$

contribute. Here  $\sum_{i(j)}$  is a sum over the set of neighbors  $i$  of site  $j$ .

A term of the effective Hamiltonian  $\mathcal{H}_{\text{eff}}$  corresponding to the  $j$ -th element in the sum reads

$$-\frac{t^2}{U} \sum_{i(j), \sigma_1, \sigma_2} c_{i,\sigma_1}^\dagger c_{j,\sigma_1} n_{j,\sigma} n_{j,-\sigma} c_{j,\sigma_2}^\dagger c_{i,\sigma_2}$$

There are only four cases in which the contribution of a term of this type is nonzero.

- $\sigma = \sigma_1 = \sigma_2$

The operator in the sum then becomes

$$c_{i,\sigma}^\dagger c_{j,\sigma} n_{j,\sigma} n_{j,-\sigma} c_{j,\sigma}^\dagger c_{i,\sigma} = n_{i,\sigma} n_{j,-\sigma} c_{j,\sigma} n_{j,\sigma} c_{j,\sigma}^\dagger$$

Now, we use a fermionic operator identity:

$$\begin{aligned}cn &= cc^\dagger c = (1 - c^\dagger c)c = c \\ \implies c_{j,\sigma} n_{j,\sigma} c_{j,\sigma}^\dagger &= c_{j,\sigma} c_{j,\sigma}^\dagger = 1 - n_{j,\sigma}\end{aligned}$$

The term of the Hamiltonian corresponding to this first case then takes on the form

$$n_{i,\sigma} n_{j,-\sigma} (1 - n_{j,\sigma})$$

We can further simplify this term by noting that in the subspace where  $\mathcal{H}_{\text{eff}}$  acts, every site is occupied by only a single electron so that

$$n_{j,\sigma} + n_{j,-\sigma} = 1 \iff 1 - n_{j,\sigma} = n_{j,-\sigma}$$

Since, for fermions we have that  $\hat{n} = \hat{n}^k$ , whichever the power  $k \in \mathbb{N}$ , the final form of the sought term of the Hamiltonian is

$$n_{i,\sigma} n_{j,-\sigma}$$

- $-\sigma = \sigma_1 = \sigma_2$

The contribution to the Hamiltonian is exactly of the same form but making  $\sigma \mapsto -\sigma$ :

$$n_{i,-\sigma} n_{j,\sigma}$$

- $\sigma = -\sigma_1 = \sigma_2$

We can use the same reasoning as we did for the first term to obtain

$$\begin{aligned} & c_{i,-\sigma}^\dagger c_{j,-\sigma} n_{j,\sigma} n_{j,-\sigma} c_{j,\sigma}^\dagger c_{i,\sigma} \\ &= c_{i,-\sigma}^\dagger c_{i,\sigma} \underbrace{c_{j,-\sigma} n_{j,-\sigma}}_{c_{j,-\sigma}} \underbrace{n_{j,\sigma} c_{j,\sigma}^\dagger}_{c_{j,\sigma}^\dagger} \\ &= - c_{i,-\sigma}^\dagger c_{i,\sigma} c_{j,\sigma}^\dagger c_{j,-\sigma} \end{aligned}$$

- $-\sigma = -\sigma_1 = \sigma_2$

Analogously, the contribution to the Hamiltonian is

$$\begin{aligned} & c_{i,\sigma}^\dagger c_{j,\sigma} n_{j,\sigma} n_{j,-\sigma} c_{j,-\sigma}^\dagger c_{i,-\sigma} \\ &= - c_{i,-\sigma}^\dagger c_{i,\sigma} c_{j,\sigma}^\dagger c_{j,-\sigma} \end{aligned}$$

Grouping all these four terms, we obtain

$$\mathcal{H}_{\text{eff}} = \frac{2t^2}{U} \sum_{\langle i,j \rangle, \sigma} (-n_{i,\sigma} n_{j,-\sigma} + c_{i,-\sigma}^\dagger c_{i,\sigma} c_{j,\sigma}^\dagger c_{j,-\sigma}), \quad (2.73)$$

where the factor of 2 appears because for each pair of nearest neighbors  $\langle i,j \rangle$ , a term comes from the term  $n_{j,\sigma} n_{j,-\sigma}$  of the sum  $\sum_j n_{j,\sigma} n_{j,-\sigma}$ , and another term from  $n_{i,\sigma} n_{i,-\sigma}$ .

Recall the second quantized form of the spin operators:

$$\begin{cases} S_i^z = \frac{1}{2}(n_{i,\uparrow} - n_{i,\downarrow}) \\ S_i^+ = c_{i,\uparrow}^\dagger c_{i,\downarrow} \\ S_i^- = c_{i,\downarrow}^\dagger c_{i,\uparrow}, \end{cases} \quad (2.74)$$

Using these relations and that the density operator is  $n_i = n_{i,\uparrow} + n_{i,\downarrow}$ , the following relations hold

$$\begin{aligned} S_i^z S_j^z - \frac{1}{4} n_i n_j &= -\frac{1}{2}(n_{i,\uparrow} n_{j,\downarrow} + n_{i,\downarrow} n_{j,\uparrow}) \\ S_i^+ S_j^- + S_i^- S_j^+ &= c_{i,\uparrow}^\dagger c_{i,\downarrow} c_{j,\downarrow}^\dagger c_{j,\uparrow} + c_{i,\downarrow}^\dagger c_{i,\uparrow} c_{j,\uparrow}^\dagger c_{j,\downarrow} \end{aligned} \quad (2.75)$$

Thus, we may rewrite the effective Hamiltonian:

$$\mathcal{H}_{\text{eff}} = \frac{4t^2}{U} \sum_{\langle i,j \rangle} \left( S_i^z S_j^z - \frac{1}{4} n_i n_j + \frac{1}{2}(S_i^+ S_j^- + S_i^- S_j^+) \right) \quad (2.76)$$

But  $S_i^z S_j^z + \frac{1}{2}(S_i^+ S_j^- + S_i^- S_j^+) = \mathbf{S}_i \cdot \mathbf{S}_j$  and  $n_i = n_j = 1$  in the ground state subspace, so the effective Hamiltonian becomes

$$\mathcal{H}_{\text{eff}} = \frac{4t^2}{U} \sum_{\langle i,j \rangle} \left( \mathbf{S}_i \cdot \mathbf{S}_j - \frac{1}{4} \right), \quad (2.77)$$

which corresponds to the antiferromagnetic Heisenberg model:  $\mathcal{H}_{\text{Heis}} = J \sum_{\langle i,j \rangle} \mathbf{S}_i \cdot \mathbf{S}_j$ , with  $J = 4t^2/U$ . Since  $J > 0$ , the model favors configurations with antiparallel adjacent spins. There is an intuitive physical picture for this result: if two electrons on neighboring sites have parallel spins, none of the two can hop to the neighboring site due to Pauli's exclusion principle. If adjacent sites have antiparallel spins, however, it is possible for any of the two electrons to hop to the neighboring site, and an exchange process allows the system to lower its energy.

As a final remark, we note that the effective Hamiltonian we obtained corresponds to the  $\frac{t}{U} \ll 1$  limit, which is consistent since the Heisenberg model couples spins on different sites, thus it is an *atomic* model.

## Auxiliary Field Quantum Monte Carlo

### Contents

---

3.1 Trotter-Suzuki Decomposition . . . . .	46
--	----

---

The interactions between the electrons in a solid give rise to effects that arise specifically due to the many-body nature of the system. The Hubbard model is a minimal model that encapsulates electron correlations. It goes beyond the periodic ionic potential perturbation to the free electron gas or tight binding approaches, which lead to band theory. As we have seen, one obtains the Hubbard Hamiltonian by adding the simplest possible electron-electron interaction term to a tight binding Hamiltonian: an on-site interaction term that penalizes double occupancy of a site. From it, we can make predictions about properties of a strongly correlated system, namely magnetic and superconducting behavior, and metal-insulator transitions.

Auxiliary-field, or Determinant Quantum Monte Carlo <sup>1</sup> is a simulation method that is commonly used to simulate the Hubbard model, allowing one to capture the elusive effects of electron correlations, for example in the two-dimensional graphene-like nanostructures we are concerned with.

Among the various methods belonging to the family of QMC methods, AFQMC has the advantage of allowing us to circumvent the sign problem for the half filled Hubbard model. The sign problem is an uncontrolled numerical error due to the antisymmetry of the many-electron wave function, leading to oscillations in the sign of the quantities that we are interested in measuring. These oscillations deem the algorithm exponentially complex in the size of the system, in general, but it is possible to overcome this hurdle for a class of models, namely the Hubbard model at half filling. The difficulty lies in computing averages of a quantity  $X$  that is very close to zero, on average, but has a large variance, i.e.  $\sigma_X / \langle X \rangle \gg 1$ .

### 3.1 Trotter-Suzuki Decomposition

We seek a computable approximation of the projection operator  $\mathcal{P}$  defined in equation (2.26). As we shall see, it is found by using a discrete Hubbard-Stratonovich transformation. This transformation introduces an auxiliary field (consisting basically of Ising spins), and we use Monte Carlo to sample configurations from the distribution corresponding to this *classical* configuration space.

For now, let us assume half filling  $\mu = 0$ , so that there is no sign problem. In fact, many interesting phenomena occur at half filling, for example magnetic ordering and the Mott metal-insulator transition.

#### 3.1.1 Hubbard-Stratonovich transformation

In section ??, we found exact solutions for particular instances of the Hubbard model by finding a closed form for the partition function [64]. When devising a numerical method, a good sanity check is to verify that it satisfactorily approximates the partition function.

The operators  $\mathcal{H}_K$  and  $\mathcal{H}_V$  of equation (2.23) do not commute. This impedes us from factorizing the exponential of their sum  $e^{-\beta(\mathcal{H}_K + \mathcal{H}_V)}$  exactly. The Trotter-Suzuki decomposition leads to the sought approximate factorization that is used to approximate the partition function. Quantum states evolve according to

---

<sup>1</sup>AFQMC or DQMC, respectively.

$$|\psi(\tau)\rangle = e^{-\tau\mathcal{H}} |\psi(0)\rangle, \quad (3.1)$$

where  $\tau = it$  is the imaginary time. Recall that Diffusion Monte Carlo is based on this imaginary time evolution, filtering out the ground state as the state that takes longer to vanish exponentially. We now seek a finite temperature method. To find it, we invoke an analogy with the evolution of a quantum system according to the previous equation.

Taking the scalar product with a position eigenstate  $\langle \mathbf{x}|$ , we obtain  $\psi(\mathbf{x}, \tau) = \langle \mathbf{x} | \psi(\tau) \rangle$ . Using the closure relation  $\int d\mathbf{y} |\mathbf{y}\rangle \langle \mathbf{y}| = 1$ , we get

$$\psi(\mathbf{x}, \tau) = \int d\mathbf{y} \langle \mathbf{x} | e^{-\tau\mathcal{H}} |\mathbf{y}\rangle \psi(\mathbf{y}, 0) \quad (3.2)$$

The wave function at position  $\mathbf{x}$  and time  $t$  may be obtained by this equation as long as we know the wave function at  $\tau = 0$ ,  $\psi(\mathbf{y}, 0)$  for all points in space  $\mathbf{y}$ . The evolution operator matrix element, or Green function,

$$G(\mathbf{x}, \tau | \mathbf{y}, 0) \equiv \langle \mathbf{x} | e^{-\tau\mathcal{H}} |\mathbf{y}\rangle, \quad (3.3)$$

as the wave function, satisfies the Schrödinger equation, with the initial condition  $\psi(\mathbf{y}, 0) = \delta(\mathbf{x} - \mathbf{y})$ . It is then the probability of presence at  $\mathbf{x}, t$  of a wave packet centered at  $\mathbf{y}$  at  $t = 0$ . Note that the solution of the Schrödinger equation is then analogous to that of a diffusion equation (that in turn one may obtain as the continuum limit of a random walk). We may write  $G$  as a linear combination of the eigenstates of the Hamiltonian

$$G(\mathbf{x}, \tau | \mathbf{y}, 0) = \sum_{\alpha} \psi_{\alpha}^*(\mathbf{y}) \psi_{\alpha}(\mathbf{x}) e^{-E_{\alpha}\tau}, \quad (3.4)$$

where we immediately note a striking similarity with equation (2.27). The correspondence  $\psi(\mathbf{x}, \tau) \mapsto Z_{\beta}$ , where  $\tau \mapsto \beta$ , with respect to section ?? makes the analogy evident.  $\mathbf{x}$  has no correspondence because it is not a parameter, it is just an arbitrary position that we fixed for the sake of the argument.

Computing the partition function at finite temperature

$$Z_{\beta} = \text{Tr}(e^{-\beta\mathcal{H}}) \quad (3.5)$$

is analogous to computing the Green function of a quantum system evolving in imaginary time. The inverse temperature  $\beta$  now represents the imaginary time  $\tau = it$ , and  $Z_{\beta}$  may be simply thought of as the wave function of the analogous quantum system at imaginary time (temperature)  $\beta$ .

This expression is not very amenable to numerical computation since it contains an exponential of a sum of operators  $\mathcal{H}_K + \mathcal{H}_V$ , which is not factorizable and involves computing an infinite number of commutators containing these two operators, as per the Zassenhaus formula, valid for any two generic operators  $X$  and  $Y$ :

$$e^{\delta(X+Y)} = e^{\delta X} e^{\delta Y} e^{-\frac{\delta^2}{2}[X,Y]} e^{\frac{\delta^3}{6}(2[Y,[X,Y]]+[X,[X,Y]])} \\ e^{-\frac{\delta^4}{24}([[X,Y],X],X)+3[[[X,Y],X],Y]+3[[[X,Y],Y],Y]} \dots, \quad (3.6)$$

where  $\delta \in \mathbb{C}$  is an expansion parameter.

Dividing the imaginary time interval  $[0, \beta]$  into  $L$  equal sub-intervals of width  $\Delta\tau = \beta/L$ , we obtain

$$Z = \text{Tr} \left( \prod_{l=1}^L e^{-\Delta\tau \mathcal{H}} \right), \quad (3.7)$$

which is now a product of exponentials of operators multiplied by a constant that can be made small by increasing  $L$ . The Trotter-Suzuki decomposition follows from truncating equation (3.6), and keeping only the first order term in  $t$ , i.e. the one in  $\Delta\tau$  in our case.

$$Z = \text{Tr} \left( \prod_{l=1}^L e^{-\Delta\tau \mathcal{H}_K} e^{-\Delta\tau \mathcal{H}_V} \right) + \mathcal{O}(\Delta\tau^2) \quad (3.8)$$

The kinetic energy term is quadratic in the fermion operators, and is spin-independent and thus may be separated into spin up and spin down components

$$e^{-\Delta\tau \mathcal{H}_K} = e^{-\Delta\tau \mathcal{H}_{K\uparrow}} e^{-\Delta\tau \mathcal{H}_{K\downarrow}}, \quad (3.9)$$

where  $\mathcal{H}_{K_\sigma} = -t \mathbf{c}_\sigma^\dagger \mathbf{K} \mathbf{c}_\sigma$ .

The potential energy term, however, is quartic. Surprisingly, it is possible to express it in quadratic form by introducing an extra degree of freedom, the so called *Hubbard-Stratonovich (HS) field*  $\mathbf{h} \equiv (h_i)_{i=1}^N$ , in which each element is essentially an Ising spin. First, note that number operators on different sites commute, so that we have

$$e^{-\Delta\tau \mathcal{H}_V} = e^{-U \Delta\tau \sum_{i=1}^N (n_{i\uparrow} - 1/2)(n_{i\downarrow} - 1/2)} \\ = \prod_i e^{-U \Delta\tau (n_{i\uparrow} - 1/2)(n_{i\downarrow} - 1/2)} \quad (3.10)$$

Now we introduce the discrete Hubbard Stratonovich transformation for  $U > 0$  that allows us to recast the equation above in terms of a non-interacting quadratic term  $(n_{i\uparrow} - n_{i\downarrow})$ .

$$e^{-U \Delta\tau (n_{i\uparrow} - 1/2)(n_{i\downarrow} - 1/2)} = c_U \sum_{h_i=\pm 1} e^{\nu h_i (n_{i\uparrow} - n_{i\downarrow})}, \quad (3.11)$$

where  $c_U = \frac{1}{2} e^{-\frac{U\Delta\tau}{4}}$  and  $\nu = \text{arcosh}(e^{\frac{U\Delta\tau}{2}})$ .

To prove this identity, let us write down how the operators  $(n_{i\uparrow} - 1/2)(n_{i\downarrow} - 1/2)$  and  $(n_{i\uparrow} - n_{i\downarrow})$  act on a state on a given site.

$$(n_{i\uparrow} - 1/2)(n_{i\downarrow} - 1/2) \begin{cases} |\rangle = \frac{1}{4} |\rangle \\ |\uparrow\rangle = -\frac{1}{4} |\uparrow\rangle \\ |\downarrow\rangle = -\frac{1}{4} |\downarrow\rangle \\ |\uparrow\downarrow\rangle = \frac{1}{4} |\uparrow\downarrow\rangle \end{cases} \quad (3.12)$$

$$(n_{i\uparrow} - n_{i\downarrow}) \begin{cases} |\rangle = 0 |\rangle \\ |\uparrow\rangle = |\uparrow\rangle \\ |\downarrow\rangle = |\downarrow\rangle \\ |\uparrow\downarrow\rangle = 0 |\uparrow\downarrow\rangle \end{cases}$$

Now we simply compare the action of the operators on the left hand side and on the right hand side of equation (3.11) and find the desired relation by defining

$$\cosh \nu = \frac{e^\nu + e^{-\nu}}{2} \equiv e^{\frac{U\Delta\tau}{2}} \quad (3.13)$$

$$e^{-U\Delta\tau(n_{i\uparrow}-1/2)(n_{i\downarrow}-1/2)} |\psi\rangle = e^{-\frac{U\Delta\tau}{4}} |\psi\rangle, |\psi\rangle = |\rangle, |\uparrow\downarrow\rangle$$

$$e^{-U\Delta\tau(n_{i\uparrow}-1/2)(n_{i\downarrow}-1/2)} |\uparrow(\downarrow)\rangle = e^{\frac{U\Delta\tau}{4}} |\uparrow(\downarrow)\rangle$$

$$c_U \sum_{h_i=\pm 1} e^{\nu h_i (n_{i\uparrow} - n_{i\downarrow})} |\psi\rangle = e^{-\frac{U\Delta\tau}{4}} |\psi\rangle, |\psi\rangle = |\rangle, |\uparrow\downarrow\rangle \quad (3.14)$$

$$c_U \sum_{h_i=\pm 1} e^{\nu h_i (n_{i\uparrow} - n_{i\downarrow})} |\uparrow(\downarrow)\rangle = \frac{e^\nu + e^{-\nu}}{2} e^{-\frac{U\Delta\tau}{4}} |\uparrow(\downarrow)\rangle$$

Note that we require  $U > 0$  so that there exists  $\nu \in \mathbb{R}$  such that  $\cosh \nu = e^{U\Delta\tau/2}$ . A similar reasoning could be made for  $U < 0$ . Additionally, other transformations that recast other types of quartic terms in terms of quadratic ones exist, but we shall not need them in what follows [8]. The transformation we derived is the one we will use throughout.

We have now made progress. At the expense of introducing an extra  $N$ -dimensional HS-field  $\mathbf{h}$ , we obtained an *exact* representation of the quartic term in terms of quadratic terms [64].

$$e^{-\Delta\tau\mathcal{H}_V} = \prod_{i=1}^N \left( c_U \sum_{h_i=\pm 1} e^{\nu h_i (n_{i\uparrow} - n_{i\downarrow})} \right), \quad (3.15)$$

which can be manipulated to arrive at a more compact form.

$$\begin{aligned}
e^{-\Delta\tau\mathcal{H}_V} &= (c_U)^N \sum_{h_i=\pm 1} e^{\nu h_i(n_{1\uparrow}-n_{1\downarrow})} \sum_{h_i=\pm 1} e^{\nu h_i(n_{2\uparrow}-n_{2\downarrow})} \\
&\quad \cdots \sum_{h_i=\pm 1} e^{\nu h_i(n_{N\uparrow}-n_{N\downarrow})} \\
&= (c_U)^N \sum_{h_i=\pm 1} e^{\sum_{i=1}^N [(\nu h_i(n_{i\uparrow}-n_{i\downarrow})]} \\
&\equiv (c_U)^N \text{Tr}_h e^{\sum_{i=1}^N [(\nu h_i(n_{i\uparrow}-n_{i\downarrow})]} \\
&= (c_U)^N \text{Tr}_h e^{\sum_{i=1}^N \nu h_i n_{i\uparrow}} e^{-\sum_{i=1}^N \nu h_i n_{i\uparrow}} \\
&= (c_U)^N \text{Tr}_h (e^{\mathcal{H}_{V\uparrow}} e^{\mathcal{H}_{V\downarrow}}),
\end{aligned} \tag{3.16}$$

where the spin up and spin down operators  $\mathcal{H}_{V\sigma}$  are defined as follows

$$\mathcal{H}_{V\sigma} = \sum_{i=1}^N \nu h_i n_{i\sigma} = \sigma \nu \mathbf{c}_\sigma^\dagger \mathbf{V}(\mathbf{h}) \mathbf{c}_\sigma, \tag{3.17}$$

with  $\mathbf{V}(\mathbf{h})$  being simply the HS-field put into a diagonal  $N \times N$  matrix:  $\mathbf{V}(\mathbf{h}) \equiv \text{diag}(h_1, h_2, \dots, h_N)$ .

For each imaginary time slice  $l$  (where  $l \in [1, L]$ ) we may define a HS-field  $\mathbf{h}_l$ , which in turn specifies  $\mathbf{V}_l$  and  $\mathcal{H}_{V_\sigma}^l$ . We may now replace the result of equation (3.16) in equation (3.8), and exchange the traces to obtain

$$\begin{aligned}
Z_h &= (c_U)^{NL} \text{Tr}_h \text{Tr} \left[ \underbrace{\prod_{l=1}^L \left( e^{-\Delta\tau\mathcal{H}_{K\uparrow}} e^{\mathcal{H}_{V\uparrow}^l} \right)}_{B_{l,\uparrow}(\mathbf{h}_l)} \right. \\
&\quad \left. \underbrace{\left( e^{-\Delta\tau\mathcal{H}_{K\downarrow}} e^{\mathcal{H}_{V\downarrow}^l} \right)}_{B_{l,\downarrow}(\mathbf{h}_l)} \right], \tag{3.18}
\end{aligned}$$

where all operators are now quadratic in the fermion operators:

$$\begin{aligned}
\mathcal{H}_{K\sigma} &= -t \mathbf{c}_\sigma^\dagger \mathbf{K} \mathbf{c}_\sigma \\
\mathcal{H}_{V_\sigma}^l &= \sigma \nu \mathbf{c}_\sigma^\dagger \mathbf{V}_l(\mathbf{h}_l) \mathbf{c}_\sigma
\end{aligned} \tag{3.19}$$

for  $\sigma = \pm 1$  and  $\mathbf{V}_l(\mathbf{h}_l) = \text{diag}(h_{l,1}, h_{l,2}, \dots, h_{l,N})$ .

Furthermore, we have defined the  $\mathbf{B}$ -matrices

$$\mathbf{B}_{l,\sigma}(\mathbf{h}_l) = e^{t\Delta\tau\mathbf{K}} e^{\sigma \nu \mathbf{V}_l(\mathbf{h}_l)} \tag{3.20}$$

Note that the argument of the first exponential is positive since  $\mathbf{K}$  is defined so that its entries are 0's and 1's; otherwise (defining  $\mathbf{K}$  with 0's and  $-1$ 's) it would be negative.

The problem of computing the partition has been reduced to computing the trace of a product of exponentials of quadratic forms. Thus, we may still rewrite equation (3.18) by making use of the following identity.

Let  $\mathcal{H}_l$  be quadratic forms of the fermion operators:

$$\mathcal{H}_l = c_i^\dagger (H_l)_{ij} c_j, \quad (3.21)$$

where the summation is implied, and where  $H_l$  are real matrices. Then, the following identity holds

$$\text{Tr} [e^{-\mathcal{H}_1} e^{-\mathcal{H}_2} \dots e^{-\mathcal{H}_L}] = \det(\mathbf{I} + e^{-H_L} e^{-H_{L-1}} \dots e^{-H_1}) \quad (3.22)$$

For simplicity, we present the proof for a simpler case, corresponding to a single  $\mathbf{B}$ -matrix, i.e. a product of exponentials of two quadratic operators [7]. It could then be easily extended to the more general case. Let the two arbitrary real matrices be  $\mathbf{M}$  and  $\mathbf{N}$ . Then, a particular case of the previous identity is

$$\text{Tr} [e^{-c_i^\dagger M_{ij} c_j} e^{-c_i^\dagger N_{ij} c_j}] = \det(\mathbf{I} + e^{-\mathbf{M}} e^{-\mathbf{N}}), \quad (3.23)$$

where a summation over repeated indices is implied, as it will be throughout this proof.

To prove this identity, we start by proving that

$$e^{-c_i^\dagger M_{ij} c_j} e^{-c_i^\dagger N_{ij} c_j} = e^{-\sum_\nu c_\nu^\dagger \rho_\nu c_\nu}, \quad (3.24)$$

where  $\lambda_\nu = e^{-\rho_\nu}$  are the eigenvalues of the matrix  $e^{-\mathbf{M}} e^{-\mathbf{N}}$ .

The proof consists of showing that any many-particle state are propagated in the same way when acted upon by any of these two operators, i.e. the LHS operator leads the system to the same state as the RHS operator.

A generic single-particle state reads

$$|\phi\rangle = \sum_j a_j c_j^\dagger |0\rangle, \quad (3.25)$$

where  $a_j$  are arbitrary coefficients, and  $|0\rangle$  is the vacuum state.

Let  $\{|\mu\rangle\}$  be the basis in which the matrix  $\mathbf{N}$  is diagonal. Using Dirac notation, we then have

$$\mathbf{N} = \sum_\mu |\mu\rangle n_\mu \langle \mu| \quad (3.26)$$

Defining new fermionic operators

$$\begin{aligned} c_\mu &= \sum_j \langle \mu | j \rangle c_j \\ c_\mu^\dagger &= \sum_j \langle j | \mu \rangle c_j^\dagger, \end{aligned} \quad (3.27)$$

which may be inverted to obtain

$$\begin{aligned} c_j &= \sum_{\mu} \langle j | \mu \rangle c_{\mu} \\ c_j^{\dagger} &= \sum_{\mu} \langle \mu | j \rangle c_{\mu}^{\dagger}, \end{aligned} \tag{3.28}$$

Now we prove yet another identity that goes into proving equation (3.24).

$$e^{-c_i^{\dagger} N_{ij} c_j} = \prod_{\mu} [\mathbb{1} + (e^{-n_{\mu}} - 1) c_{\mu}^{\dagger} c_{\mu}] \tag{3.29}$$

$$\begin{aligned} \exp(-c_i^{\dagger} N_{ij} c_j) &= \exp\left(-\sum_{\mu\nu} \langle \mu | i \rangle c_{\mu}^{\dagger} N_{ij} \langle j | \nu \rangle c_{\nu}\right) \\ &= \exp\left(-\sum_{ij} \sum_{\mu\nu\sigma} \langle \mu | i \rangle \langle i | \sigma \rangle c_{\mu}^{\dagger} n_{\sigma} \langle \sigma | j \rangle \langle j | \nu \rangle c_{\nu}\right), \\ &\quad (\text{using the closure relation } \sum_i |i\rangle \langle i| = \mathbb{1}) \\ &= \exp\left(-\sum_{\mu\nu\sigma} \overbrace{\langle \mu | \sigma \rangle}^{\delta_{\mu\sigma}} c_{\mu}^{\dagger} n_{\sigma} \overbrace{\langle \sigma | \nu \rangle}^{\delta_{\sigma\nu}} c_{\nu}\right) \\ &= \exp\left(-\sum_{\mu} c_{\mu}^{\dagger} n_{\mu} c_{\mu}\right) \\ &= \prod_{\mu} e^{-n_{\mu} \hat{n}_{\mu}} \\ &= \prod_{\mu} [\mathbb{1} + (-n_{\mu} \hat{n}_{\mu} + \frac{n_{\mu}^2}{2!} \hat{n}_{\mu}^2 - \frac{n_{\mu}^3}{3!} \hat{n}_{\mu}^3 + \dots)] \\ &= \prod_{\mu} [\mathbb{1} + (-n_{\mu} + \frac{n_{\mu}^2}{2!} - \frac{n_{\mu}^3}{3!} + \dots) \hat{n}_{\mu}] \\ &\quad (\text{since } \hat{n} = \hat{n}^k \text{ for all } k \in \mathbb{N} \text{ for fermions since } n = 0, 1) \\ &= \prod_{\mu} [\mathbb{1} + (e^{-n_{\mu}} - 1) c_{\mu}^{\dagger} c_{\mu}] \quad \square \end{aligned}$$

Let

$$|\phi\rangle = \sum_j a_j c_j^{\dagger} |0\rangle \tag{3.30}$$

be an arbitrary many-particle state.

Now we use the previous identity to prove that applying the operator of equation (3.29) to  $|\phi\rangle$  we obtain

$$e^{-c_i^{\dagger} N_{ij} c_j} |\phi\rangle = \sum_j a'_j c_j^{\dagger} |0\rangle, \tag{3.31}$$

with

$$a'_j = \sum_i (e^{-B})_{ji} a_i \tag{3.32}$$

We start by writing  $|\phi\rangle$  in the basis  $\{|\mu\rangle\}$  (in which  $N$  is diagonal).

$$|\phi\rangle = \sum_{i,\mu} a_i \langle \mu | i \rangle c_\mu^\dagger |0\rangle \quad (3.33)$$

Then, we apply the RHS of equation (3.29) to  $|\phi\rangle$  written in this basis.

$$\begin{aligned} & \sum_\nu \left[ \mathbb{1} + (e^{-n_\mu} - 1)c_\nu^\dagger c_\nu \right] c_\mu^\dagger |0\rangle \\ &= \left[ \mathbb{1} + (e^{-n_\mu} - 1)c_\mu^\dagger c_\mu \right] c_\mu^\dagger |0\rangle \\ &= c_\mu^\dagger |0\rangle + (e^{-n_\mu-1} - 1)c_\mu^\dagger |0\rangle \\ &= c_\mu^\dagger e^{-n_\mu} |0\rangle \end{aligned} \quad (3.34)$$

$$\begin{aligned} & \sum_\nu \left[ \mathbb{1} + (e^{-n_\mu} - 1)c_\nu^\dagger c_\nu \right] |\phi\rangle \\ &= \sum_{i\mu} \langle \mu | i \rangle a_i e^{-n_\mu} c_\mu^\dagger \\ &= \sum_{j\mu i} \langle j | \mu \rangle e^{-n_\mu} \langle \mu | i \rangle a_i |j\rangle \\ &= \sum_{ji} \underbrace{\sum_{\mu\nu} \langle j | \mu \rangle e^{-N_{\mu\nu}} \langle \nu | i \rangle a_i}_{(e^{-\mathbf{N}})_{ji}} |j\rangle \\ &= \sum_j a'_j c_j^\dagger |0\rangle \end{aligned} \quad (3.35)$$

Similarly, by repeating the procedure performing a change of basis to the eigenbasis of  $\mathbf{M}$ , we obtain the more general relation

$$\begin{aligned} & e^{-c_i^\dagger M_{ij} c_j} e^{-c_i^\dagger N_{ij} c_j} |\phi\rangle = \sum_j a''_j c_j^\dagger |0\rangle \\ & a''_j = \sum_i (e^{-\mathbf{M}} e^{-\mathbf{N}})_{ji} a_i \end{aligned} \quad (3.36)$$

The amplitude of a propagated state is given by multiplying the initial amplitude by the matrix  $e^{-\mathbf{M}} e^{-\mathbf{N}}$ , whichever the basis we choose. Then, since equation (3.36) holds in particular for the choice of the eigenbasis of  $e^{-\mathbf{M}} e^{-\mathbf{N}}$  as our basis of single-particle states, if we start with an eigenstate

$$|\phi\rangle = c_\nu^\dagger |0\rangle, \quad (3.37)$$

then the amplitude of the propagated state will be given by

$$(e^{-\mathbf{M}} e^{-\mathbf{N}})_{\nu\nu} = e^{-\rho_\nu}, \quad (3.38)$$

the same as we would obtain from equation (3.24). Clearly, if we start with a state that is an arbitrary combination of states of the eigenbasis, we would obtain the identity (3.24).

The identity was proven for a single-particle state. Does it generalize to more than one particle? As we did before, we start with propagation by a single factor  $e^{-\mathbf{N}}$ . Take a two-particle state

$$|\phi\rangle = c_{\mu_1}^\dagger c_{\mu_2}^\dagger |0\rangle \quad (3.39)$$

Now propagate it with  $\mathbf{N}$ , i.e.

$$\begin{aligned} e^{-c_i^\dagger N_{ij} c_j} |\phi\rangle &= \prod_\mu \left[ 1 + (e^{-n_\mu} - 1) c_\mu^\dagger c_\mu \right] c_{\mu_1}^\dagger c_{\mu_2}^\dagger |0\rangle \\ &= e^{-n_{\mu_1}} e^{-n_{\mu_2}} c_{\mu_1}^\dagger c_{\mu_2}^\dagger |0\rangle, \end{aligned} \quad (3.40)$$

where we simply note that by similar reasoning to the previous case, we would in equation (3.34) keep two terms corresponding to  $\mu_1 \neq \mu_2$ . If  $\mu_1 = \mu_2$ , then both sides are equal to zero due to Pauli's exclusion principle and the equality holds trivially. This reasoning clearly generalizes to an arbitrary superposition of many-particle states. Moreover, we proved the result for a product of two factors  $e^{-\mathbf{M}} e^{-\mathbf{N}}$ , but it is also easy to see that by successive changes of basis, we could extend our result to an arbitrary number of factors.

To complete our proof of the identity (3.23) that is so crucial in formulating AFQMC, we use the auxiliar identity we just proved (3.24).

$$\begin{aligned} \text{Tr} \left[ e^{-\sum_\nu c_\nu^\dagger \rho_\nu c_\nu} \right] &= \text{Tr} \left[ \prod_\nu e^{-c_\nu^\dagger \rho_\nu c_\nu} \right] \text{ since } [\hat{n}_\mu, \hat{n}_\nu] = 0 \\ &= \prod_\nu (1 + e^{-\rho_\nu}) = \det[\mathbf{I} + e^{-\mathbf{M}} e^{-\mathbf{N}}], \quad \square \end{aligned} \quad (3.41)$$

where the last equality stems from the fact that the determinant of a diagonal matrix is just the product of the eigenvalues.

When applied to our problem, equation (3.22) essentially makes the computation of the trace possible! Note that if we were to compute it naively, we would soon run out of computer memory. The dimension of the Hilbert space of the Hubbard model is exponential in  $N$  (actually  $4^N$ ), where  $N$  is the number of lattice sites. The determinant is calculated for a matrix whose size is polynomial in  $N$ .

Equation (3.22) allows us to write the partition function (3.18) in computable form

$$\begin{aligned} Z_{\mathbf{h}} &= \text{Tr}_{\mathbf{h}} \left[ (c_U)^{NL} \det[\mathbf{M}_\uparrow(\mathbf{h})] \det[\mathbf{M}_\downarrow(\mathbf{h})] \right] \\ &\equiv \text{Tr}_{\mathbf{h}} \left[ \tilde{\rho}_{\text{eff}}(\mathbf{h}) \right], \end{aligned} \quad (3.42)$$

where the fermion matrices  $\mathbf{M}_\sigma$  are defined in terms of the  $\mathbf{B}$ -matrices for a given spin  $\sigma$  and a given HS-field  $\mathbf{h}$ :

$$\mathbf{M}_\sigma(\mathbf{h}) = \mathbf{I} + \mathbf{B}_{L,\sigma}(h_L) \mathbf{B}_{L-1,\sigma}(h_{L-1}) \dots \mathbf{B}_{1\sigma}(h_1) \quad (3.43)$$

Equation (3.42) defines an effective density matrix (now a function!)  $\tilde{\rho}_{\text{eff}}(\mathbf{h})$  in the HS-field space.

The computable approximation of the distribution operator  $\mathcal{P}$  corresponding to this partition function is

$$P(\mathbf{h}) = \frac{A}{Z_h} \det[\mathbf{M}_\uparrow(\mathbf{h})] \det[\mathbf{M}_\downarrow(\mathbf{h})], \quad (3.44)$$

where  $A = (c_U)^{NL}$  is a normalization constant. This is now a distribution function over configurations  $\mathbf{h}$  since the problem is classical!

For the particular case of no interactions  $U = 0$ , we have that  $\nu = 0$ , and  $\mathbf{M}_\sigma(\mathbf{h})$  are constant matrices, independent of the HS-field. The Trotter-Suzuki approximation then becomes exact and the Hubbard Hamiltonian may be simulated exactly after evaluating  $\mathbf{M}_\sigma(\mathbf{h})$  a single time. No updates are required.

As a final remark, note that we managed to map a quantum problem to a classical problem in higher dimension. The degrees of freedom of the quantum problem correspond to the  $i$  indices of the  $c$ -operators. In our formulation, an additional imaginary time slice index  $l$  was introduced, leading to a mapping that is not specific to the Hubbard model, but that actually applies very generally for any quantum system.

### 3.1.1.A Monte Carlo sampling of the HS-field

The computational problem is now that of sampling configurations of the  $\mathbf{h}$  field drawn from the distribution  $P(\mathbf{h})$  using *Classical* Monte Carlo. The size of the state space has been (hopefully) reduced to  $2^{NL}$  (assuming that  $L < N$ ).

It remains to choose a dynamics and a sampling scheme. The simplest strategy to change from a configuration  $\mathbf{h}$  to a new one  $\mathbf{h}'$  is single spin-flip dynamics. We choose a random point  $(l, i)$ , and we flip the spin at that “site”

$$h'_{l,i} = -h_{l,i}, \quad (3.45)$$

keeping all others unchanged.

The most common scheme to ensure that the distribution of the accepted sample is  $P(\mathbf{h})$  is the Metropolis-Hastings algorithm.

After the warm-up steps, i.e. after we ensure that we are correctly sampling from the required distribution, we may perform measurements, waiting for some (Monte Carlo) time before each of them to ensure that the correlations within the sample are negligible. Let the total number of Monte Carlo steps (warm-up  $W$  + measurement  $M$ ) be  $S = W + M$ . The idea is that we run the algorithm for  $W$  steps, before starting the measurements. Then we measure the state of the system every  $2\tau$  steps, where  $\tau$  is the correlation time, i.e. the time it takes for some representative correlation function to drop to  $e^{-1}$  its original value.

The Metropolis acceptance/rejection scheme leads to a rank-one update of the matrices  $\mathbf{M}_\sigma(\mathbf{h})$ , which affords an efficient evaluation of the acceptance ratio  $a_{l,i}$  [64].

        end if
        if  $l = L$  then
             $l = 1, i = 1$ 
        end if
25:   end if
end for

```

---

Consider two matrices  $\mathbf{A}_1, \mathbf{A}_2$  written in the form

$$\mathbf{A}_{1,2} = \mathbf{I} + \mathbf{F}\mathbf{V}_{1,2}, \quad (3.46)$$

where  $\mathbf{F}$  is some matrix.  $\mathbf{V}_{1,2}$  are diagonal and non-singular and differ only in the (1, 1) entry, so that

$$\mathbf{V}_1^{-1}\mathbf{V}_2 = \mathbf{I} + \alpha_1 \mathbf{e}_1 \mathbf{e}_1^T, \quad (3.47)$$

where  $\mathbf{e}_1$  is a vector corresponding to the first column of the identity matrix  $\mathbf{I}$ , and

$$\alpha_1 = \frac{V_2(1, 1)}{V_1(1, 1)} - 1$$

Then,  $\mathbf{A}_2$  is clearly a rank-one update of  $\mathbf{A}_1$ .

$$\begin{aligned} \mathbf{A}_2 &= \mathbf{I} + \mathbf{F}\mathbf{V}_1 + \mathbf{F}\mathbf{V}_1(\mathbf{V}_1^{-1}\mathbf{V}_2 - \mathbf{I}) \\ &= \mathbf{A}_1 + \alpha_1(\mathbf{A}_1 - \mathbf{I})\mathbf{e}_1\mathbf{e}_1^T \\ &= \mathbf{A}_1[\mathbf{I} + \alpha_1(\mathbf{I} - \mathbf{A}_1^{-1})\mathbf{e}_1\mathbf{e}_1^T] \end{aligned}$$

Using the identity  $\det[\mathbf{I} + \mathbf{x}\mathbf{y}^T] = 1 + \mathbf{y}^T\mathbf{x}$  for any two column vectors, we may write the ratio of the determinants of matrices  $\mathbf{A}_1$  and  $\mathbf{A}_2$  as

$$r_1 = \frac{\det[\mathbf{A}_2]}{\det[\mathbf{A}_1]} = 1 + \alpha_1(1 - \mathbf{e}_1^T \mathbf{A}_1^{-1} \mathbf{e}_1), \quad (3.48)$$

which reduces the computation of the ratio  $r_1$  to computing the  $(1, 1)$  entry of  $\mathbf{A}^{-1}$ .

Now we generalize this idea for a sequence of matrices  $\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_i, \dots, \mathbf{A}_n$  generated by successive rank-one updates:  $\mathbf{A}_{i+1} = \mathbf{I} + \mathbf{F}\mathbf{V}_{i+1}$ ,  $i = 1, 2, \dots, n - 1$ , with

$$\mathbf{V}_i^{-1}\mathbf{V}_{i+1} = \mathbf{I} + \alpha_i \mathbf{e}_i \mathbf{e}_i^T \quad \alpha_i = \frac{\mathbf{V}_{i+1}(1, 1)}{\mathbf{V}_i(1, 1)} - 1 \quad (3.49)$$

The Sherman-Morrison-Woodbury formula gives an expression for the inverse of  $\mathbf{A}_2$  as a rank-one update of  $\mathbf{A}_1^{-1}$ .

$$\begin{aligned} \mathbf{A}_2^{-1} &= \left[ \mathbf{I} - \frac{\alpha_1}{r_1} (\mathbf{I} - \mathbf{A}_1^{-1}) \mathbf{e}_1 \mathbf{e}_1^T \right] \mathbf{A}_1^T \\ &= \mathbf{A}_1^{-1} - \frac{\alpha_1}{r_1} \mathbf{u}_1 \mathbf{w}_1^T, \end{aligned} \quad (3.50)$$

where

$$\mathbf{u}_1 = (\mathbf{I} - \mathbf{A}_1^{-1}) \mathbf{e}_1 \quad \mathbf{w}_1 = (\mathbf{A}_1^{-1})^T \mathbf{e}_1$$

Using equation (3.48), we find the updates

$$\begin{aligned} r_i &= \frac{\det[\mathbf{M}_{i+1}]}{\det[\mathbf{M}_i]} = 1 + \alpha_i (1 - \mathbf{e}_i^T \mathbf{A}_i^{-1} \mathbf{e}_i), \text{ and} \\ \mathbf{M}_{i+1}^{-1} &= \mathbf{M}_i^{-1} - \frac{\alpha_i}{r_i} \mathbf{u}_i \mathbf{w}_i^T, \end{aligned} \quad (3.51)$$

where  $\mathbf{u}_i = (\mathbf{I} - \mathbf{A}_i^{-1}) \mathbf{e}_i$  and  $\mathbf{w}_i = (\mathbf{A}_i^{-1})^T \mathbf{e}_i$ .

It is possible to generalize this procedure to compute the inverse of  $\mathbf{M}_k$  as a rank- $(k - 1)$  update of  $\mathbf{A}_1^{-1}$ :

$$\mathbf{M}_k^{-1} = \mathbf{M}_1^{-1} - \mathbf{U}_{k-1} \mathbf{D}_k \mathbf{W}_{k-1}^T, \quad (3.52)$$

where

$$\mathbf{U}_k = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_{k-1}] \quad \text{and} \quad \mathbf{W} = [\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_{k-1}], \quad (3.53)$$

and  $\mathbf{D}_k = \text{diag}(\alpha_1/r_1, \alpha_2/r_2, \dots, \alpha_{k-1}/r_{k-1})$ .

### 3.1.1.B Making measurements

In QMC simulations, physical observables are extracted by measuring them directly over the course of the sampling of the configuration space. The single-particle (equal time) Green's Function is useful to obtain quantities such as density and kinetic energy. It turns out that it is simply the inverse of the  $\mathbf{M}$ -matrix that we already compute to obtain the acceptance ratio at each step.

$$\begin{aligned}
G_{ij}^\sigma &= \left\langle c_{i\sigma} c_{j\sigma}^\dagger \right\rangle_{\mathbf{h}} \\
&= \left( M_\sigma^{-1}(\mathbf{h}) \right)_{ij} \\
&= \left( [\mathbf{I} + \mathbf{B}_{L,\sigma}(h_L) \mathbf{B}_{L-1,\sigma}(h_{L-1}) \dots \mathbf{B}_{1,\sigma}(h_1)]^{-1} \right)_{ij}
\end{aligned} \tag{3.54}$$

The equal time Green's function is a fermion average for a given HS-field configuration [65]. The corresponding thermal average is given by

$$\begin{aligned}
\left\langle c_i c_j^\dagger \right\rangle &= \frac{1}{Z} \text{Tr} \left[ e^{-\beta \mathcal{H}} c_i c_j^\dagger \right] \\
&= \frac{1}{Z} \text{Tr}_{\mathbf{h}} \text{Tr} \left[ c_{i\sigma} c_{j\sigma}^\dagger \prod_{l=1}^L B_{l,\uparrow}(\mathbf{h}_l) B_{l,\downarrow}(\mathbf{h}_l) \right],
\end{aligned} \tag{3.55}$$

The density matrix  $e^{-\beta \mathcal{H}}$  may be written as a trace over HS-field configurations of a product of L factors corresponding to each imaginary time slice. Recall equation (3.18): the partition function Z is just the trace over the Hilbert space of the aforementioned density matrix. Equivalently, it may be thought of as a trace over HS-field configurations of the effective density matrix  $\hat{\rho}_{\text{eff}}(\mathbf{h})$  defined in equation (3.42).

The Green's function is defined for fixed  $\mathbf{h}$ . Omitting the spin index  $\sigma$ , without loss of generality, we obtain

$$\begin{aligned}
G_{ij} &\equiv \left\langle c_i c_j^\dagger \right\rangle_{\mathbf{h}} = \frac{\text{Tr}[\mathbf{B}_L(h_l) \mathbf{B}_{L-1}(h_{l-1}) \dots \mathbf{B}_1(h_1) c_i c_j^\dagger]}{\tilde{\rho}_{\text{eff}}} \\
&= \frac{\text{Tr}[\mathbf{B}_L \mathbf{B}_{L-1} \dots \mathbf{B}_1 c_i c_j^\dagger]}{\text{Tr}[\mathbf{B}_L \mathbf{B}_{L-1} \dots \mathbf{B}_1]}
\end{aligned} \tag{3.56}$$

The trace is evaluated by changing to a basis  $\{|\alpha\rangle\}$ , where  $c_i$  is diagonal and then repeating the procedure for  $c_j^\dagger$ , now changing again to a basis  $\{|\beta\rangle\}$ , where  $c_j^\dagger$  is diagonal. Using equation (3.28), we obtain

$$\left\langle c_i c_j^\dagger \right\rangle_{\mathbf{h}} = \frac{\sum_{\alpha,\beta} \langle i|\alpha\rangle \langle \beta|j\rangle \text{Tr}[c_\alpha c_\beta^\dagger \mathbf{B}_L \mathbf{B}_{L-1} \dots \mathbf{B}_1]}{\text{Tr}[\mathbf{B}_L \mathbf{B}_{L-1} \dots \mathbf{B}_1]} \tag{3.57}$$

After taking the trace, (on the diagonal basis) the only nonzero contribution will be for  $\alpha = \beta$ . When  $c_\alpha c_\beta^\dagger$  acts on the bra to its left, only that term survives in the sum since  $c_\alpha$  is a diagonal operator in the basis  $\{|\alpha\rangle\}$ . On the other hand, the second equality in equation (3.41) gives the contribution to the trace of the exponential of  $c_\alpha^\dagger c_\alpha$  appearing in the  $\mathbf{B}$ -matrices.

$$\text{Tr}[\mathbf{B}_L \mathbf{B}_{L-1} \dots \mathbf{B}_1] = \prod_\nu (1 + e^{-\rho_\nu}), \tag{3.58}$$

where  $\{|\nu\rangle\}$  is the basis in which the product of the  $\mathbf{B}$ 's is diagonal.

$$\begin{aligned}
\langle c_i c_j^\dagger \rangle_h &= \sum_{\alpha} |\alpha\rangle\langle i| \frac{\text{Tr}[c_\alpha c_\alpha^\dagger \mathbf{B}_L \mathbf{B}_{L-1} \dots \mathbf{B}_1]}{\text{Tr}[\mathbf{B}_L \mathbf{B}_{L-1} \dots \mathbf{B}_1]} |j\rangle\langle \alpha| \\
&= \sum_{\alpha} |\alpha\rangle\langle i| \frac{\text{Tr}[(\mathbb{1} - c_\alpha^\dagger c_\alpha) \mathbf{B}_L \mathbf{B}_{L-1} \dots \mathbf{B}_1]}{\text{Tr}[\mathbf{B}_L \mathbf{B}_{L-1} \dots \mathbf{B}_1]} |j\rangle\langle \alpha| \\
&= \sum_{\alpha} |\alpha\rangle\langle i| 1 - \frac{\text{Tr}[c_\alpha^\dagger c_\alpha e^{-\Delta\tau\hat{h}}]}{\text{Tr}[e^{-\Delta\tau\hat{h}}]} |j\rangle\langle \alpha| \\
&= \sum_{\alpha} |\alpha\rangle\langle i| 1 - \frac{1}{1 + e^{\Delta\tau\varepsilon_{\alpha}}} |j\rangle\langle \alpha| \\
&= \sum_{\alpha} |\alpha\rangle\langle i| \frac{e^{\Delta\tau\varepsilon_{\alpha}}}{1 + e^{\Delta\tau\varepsilon_{\alpha}}} |j\rangle\langle \alpha| \\
&= \sum_{\alpha} |\alpha\rangle\langle i| \frac{1}{1 + e^{-\Delta\tau\varepsilon_{\alpha}}} |j\rangle\langle \alpha| \\
&= \left[ \frac{1}{\mathbf{B}_L \mathbf{B}_{L-1} \dots \mathbf{B}_1} \right]_{ij},
\end{aligned} \tag{3.59}$$

where in the fourth equality we used an analogy with the Fermi function defined as

$$f_{\alpha} = \frac{\text{Tr}[e^{-\beta\mathcal{H}} \hat{n}_{\alpha}]}{\text{Tr}[e^{-\beta\mathcal{H}}]} = (1 + e^{\beta\varepsilon_{\alpha}})^{-1} \tag{3.60}$$

for  $\mu = 0$  and with  $\beta \mapsto \Delta\tau$ . The product of  $\mathbf{B}$ -matrices was written as the exponential  $e^{-\Delta\tau\hat{h}}$ , which can be done because we have shown before that it is possible to diagonalize the product in a basis in which the trace amounts to the simple form of equation (3.58).

An alternative way of arriving to this result is to note that in the expression we obtain in the second equality, only the term  $\nu = \alpha$  from equation (3.58) contributes [65], leading to the final result with  $\rho_{\alpha} = \Delta\tau\varepsilon_{\alpha}$ .

The electron density may be obtained from the Green function

$$\rho_{i\sigma} = \langle c_{i\sigma}^\dagger c_{i\sigma} \rangle = 1 - \langle c_{i\sigma} c_{i\sigma}^\dagger \rangle = 1 - G_{ii}^{\sigma}, \tag{3.61}$$

It is natural to think of averaging this over the lattice, and over the spins. This is justified by the fact that the Hubbard Hamiltonian is translationally invariant. Thus,  $\rho_{i\sigma}$  should be independent of the spatial site. This statement is strict when exactly solving the model, but it becomes only approximate, i.e. valid only on average in our simulations. Thus, we take the average

$$\rho = \frac{1}{2N} \sum_{\sigma} \sum_{i=1}^N \rho_{i\sigma} \tag{3.62}$$

in an attempt to reduce statistical errors.

One must pay attention to the symmetry of the model at hand, since a similar model for a disordered system including randomness would not be translationally invariant anymore. Moreover, it is implicit that  $\rho_{i\sigma}$  is already averaged over the HS-field configurations that were sampled through the simulation.

The average kinetic energy is similarly obtained.

$$\begin{aligned}\langle \mathcal{H}_K \rangle &= -t \sum_{\langle i,j \rangle, \sigma} \left\langle (c_{i\sigma}^\dagger c_{j\sigma} + c_{j\sigma}^\dagger c_{i\sigma}) \right\rangle \\ &= t \sum_{\langle i,j \rangle, \sigma} (G_{ij}^\sigma + G_{ji}^\sigma),\end{aligned}\tag{3.63}$$

where the minus sign is due to the switching of the order of the operators bringing the  $c^\dagger$  to the right.

### 3.1.1.C Correlation functions

One of the most important goals of QMC simulations is to inspect the system for order of various types, and to find associated phase transitions. This is done by computing correlation functions  $C(j)$ , measuring how correlated two sites separated by a distance  $j$  are.

$$C(j) = \langle \mathcal{O}_{i+j} \mathcal{O}_i^\dagger \rangle - \langle \mathcal{O}_{i+j} \rangle \langle \mathcal{O}_i^\dagger \rangle,\tag{3.64}$$

where  $\mathcal{O}$  is an operator corresponding to the order parameter of the phase transition. For example, we might be looking for magnetic order, in which case the relevant operators are  $\mathcal{O}_i = n_{i\uparrow} - n_{i\downarrow}$ ,  $\mathcal{O}_i^\dagger = n_{i\uparrow} - n_{i\downarrow}$ , or superconductivity, where we would like to measure correlations in fermion pair formation:  $\mathcal{O}_i = c_{i\downarrow} c_{i\uparrow}$ ,  $\mathcal{O}_i^\dagger = c_{i\uparrow}^\dagger c_{i\downarrow}^\dagger$ .

In general, we expect a high temperature disordered phase, for which correlations decay exponentially  $C(j) \propto e^{-j/\xi}$ , where  $\xi$  is a characteristic length called the correlation length. At some point, there can be a transition to a low temperature phase, where  $C(j) \propto m^2$ , where  $m$  is the order parameter for the transition. Right at the transition, that is at  $T = T_c$ , there might be singular behavior. In continuous phase transitions, the correlation length diverges  $\xi \propto (T - T_c)^{-\nu}$ , and the correlations decay slower (in fact algebraically):  $C(j) \propto j^{-\eta}$ , in an intermediate behavior between exponential decay and a constant. The *critical* exponents  $\nu$ , and  $\eta$  are characteristic of the transition, or more accurately, of the universality class it belongs to.

The behavior of all these quantities on finite lattices does not precisely correspond to the infinite system behavior. The tails of the functions, i.e. the  $j \rightarrow \infty$  limit is not well captured. Finite-size scaling is a method to improve on these predictions.

To evaluate correlation functions we use Wick's theorem. Expectations of more than two fermion creation and annihilation operators reduce to products of expectations of pairs of creation and annihilation operators. For example, for pair order:

$$\langle C(j) \rangle = \langle c_{i+j,\downarrow} c_{i+j,\uparrow} c_{i,\uparrow}^\dagger c_{i,\downarrow}^\dagger \rangle\tag{3.65}$$

How would one measure a correlation function experimentally? Fortunately, there is a quantity that is easy to measure called structure factor, which is just the Fourier transform of the correlation function

$$S(q) = \sum_j e^{iqj} C(j)\tag{3.66}$$

The accuracy of QMC simulations can be evaluated by comparing the results for correlation functions with the corresponding structure factors, which can be measured experimentally.

*Applying all this to something*

## 6.1 One-dimensional Hubbard Chain

## 6.2 Square lattice

## 6.3 Honeycomb lattice

## 6.4 Nanoribbon

In this section, we apply our code to the case of honeycomb lattice with boundary conditions corresponding to a nanoribbon.

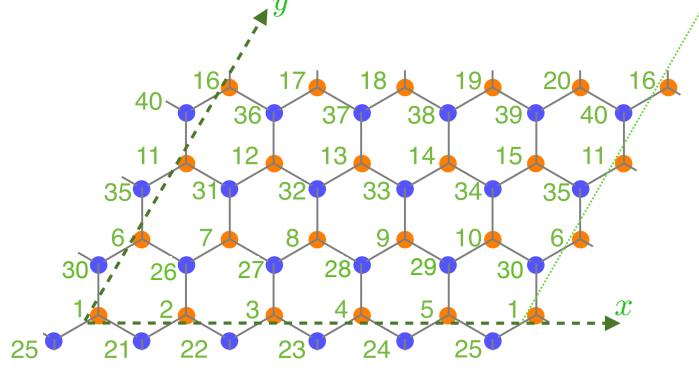

An example of an application of a QMC technique is the simulation of electron correlations in a transition metal dichalcogenide (TMD) nanoribbon, a two-dimensional nanostructure made out of some graphene-like compound [31, 35, 36, 41, 42]. The structure is much longer on one direction than on the other, resembling a ribbon, hence its name. The electronic states that accumulate on the edges of this ribbon might lead to interesting magnetic behavior in these TMD nanostructures (as they do in the analogous graphene nanostructures[37]) and this possibility remains unexplored numerically[38, 39]. Moreover, there is some interest in exploring the phase diagram of these systems because recent studies point at the possibility of topological superconductivity [34].

A nanoribbon is much longer on one direction than on the other, i.e.  $l \gg w$ . This condition corresponds to taking  $N_x \gg N_y$  in our conventions (see figure (6.1), where this condition is, of course, not obeyed solely for the sake of giving a visual representation of the boundary conditions, and the numbering system).

We use three coordinates to label each site on the honeycomb lattice, by taking advantage of its bipartite nature. Regarding the honeycomb lattice as two interpenetrating triangular sublattices  $A$  and  $B$ , we take the axes  $x$  and  $y$  to be along the primitive vectors of each triangular sublattice. Along the  $x$ -direction, the ribbon is supposed to be very long, which justifies the fact that we take periodic boundary conditions (PBCs). In contrast, in the narrow  $y$ -direction we take open boundary conditions (OBCs). To number the sites on the ribbon, we introduce an additional coordinate labeling the sublattice:  $z = 0$ , if the site is in sublattice  $A$ , and  $z = 1$  if the site is in sublattice  $B$ . We then adopt the numbering convention for the sites  $i = 1, \dots, 2N_x N_y$  of the lattice  $\mathcal{L}$ :

$$i(x, y, z) = N_x N_y z + N_x y + x, \quad (6.1)$$

where  $x = 0, \dots, N_x - 1$ ,  $y = 0, \dots, N_y - 1$ , and  $z = 0, 1$  define each element  $\mathbf{r} = (x, y, z) \in \mathcal{L}$ .

**Figure 6.1:** An illustration of the boundary conditions on the nanoribbon for  $N_x = 5$ ,  $N_y = 4$ . Let the orange circles correspond to sublattice  $A$ , and the blue circles correspond to sublattice  $B$ .

The geometry of the system appears through the hopping matrix  $\mathbf{K}$  in our code. The elements of the hopping matrix are simply defined by the indicator function:  $K_{ij} = \mathbb{1}_{\langle j_i \rangle}(i)$ , where  $\langle j_i \rangle$  is the set of neighbors  $j$  of site  $i$ . This numbering system makes it straightforward to find the neighbors of each site. Let us begin by considering a site that is not on a zigzag edge. There are four possible cases. For example, for

$$z_i = 0, y_i \neq N_y - 1, x_i \neq 0,$$

we have  $\langle j_i \rangle = \{j(\mathbf{r})\}$ , with  $\mathbf{r}$  in

$$\left\{ \mathbf{r}_j \in \mathcal{L} \mid z_j = 1 \wedge \left[ \left( y_j = y_i \wedge (x_j = x_i \vee x_j = x_i - 1) \right) \vee \left( y_j = y_i + 1 \wedge x_j = x_i - 1 \right) \right] \right\}$$

As opposed to the sites of a honeycomb lattice with PBCs, which have 3 neighbors, the sites of the zigzag edges have only 2 neighbors. Again, there are four possible cases. For example, for

$$z_i = 0, y_i = N_y - 1, x_i \neq 0,$$

we have  $\langle j_i \rangle = \{j(\mathbf{r})\}$ , with  $\mathbf{r}$  in

$$\left\{ \mathbf{r}_j \in \mathcal{L} \mid z_j = 1 \wedge y_j = y_i \wedge (x_j = x_i \vee x_j = x_i - 1) \right\}$$

We summarize these and the remaining cases in the following table.

**Table 6.1:** Nearest neighbors on the nanoribbon.

PBCs				OBCs			
Case	$z_j$	$y_j$	$x_j$	Case	$z_j$	$y_j$	$x_j$
$z_i = 0, y_i \neq N_y - 1, x_i \neq 0$	1	$y_i$	$x_i$	$z_i = 0, y_i = N_y - 1, x_i \neq 0$	1	$y_i$	$x_i$
		$y_i + 1$	$x_i - 1$				$x_i - 1$
$z_i = 0, y_i \neq N_y - 1, x_i = 0$	1	$y_i$	0	$z_i = 0, y_i = N_y - 1, x_i = 0$	1	$y_i$	0
		$y_i + 1$	$N_x - 1$				$N_x - 1$
$z_i = 1, y_i \neq 0, x_i \neq N_x - 1$	0	$y_i$	$x_i$	$z_i = 1, y_i = 0, x_i \neq N_x - 1$	0	$y_i$	$x_i$
		$y_i - 1$	$x_i + 1$				$x_i + 1$
$z_i = 1, y_i \neq 0, x_i = N_x - 1$	0	$y_i$	$N_x - 1$	$z_i = 1, y_i = 0, x_i = N_x - 1$	0	$y_i$	0
		$y_i - 1$	0				$N_x - 1$

# Hartree-Fock Approximation and the Self Consistent Field Method

In the mean field approximation, the quartic term of the interaction part of the Hamiltonian

$$V_{\text{int}} = \frac{1}{2} V_{\nu' \mu'}^{\nu \mu} c_{\nu}^{\dagger} c_{\mu}^{\dagger} c_{\mu'} c_{\nu'},$$

becomes a sum of all possible 2-body terms (note that terms of the type  $\langle cc \rangle$  and  $\langle c^{\dagger}c^{\dagger} \rangle$  must vanish since they do not conserve the number of particles).

$$c_{\nu}^{\dagger} c_{\mu}^{\dagger} c_{\mu'} c_{\nu'} \approx -\langle c_{\nu}^{\dagger} c_{\mu'} \rangle c_{\mu}^{\dagger} c_{\nu'} - \langle c_{\mu}^{\dagger} c_{\nu'} \rangle c_{\nu}^{\dagger} c_{\mu'} + \langle c_{\nu}^{\dagger} c_{\nu'} \rangle c_{\mu}^{\dagger} c_{\mu'} + \langle c_{\mu}^{\dagger} c_{\mu'} \rangle c_{\nu}^{\dagger} c_{\nu'}, \quad (\text{A.1})$$

where we ignored the constant terms which are unimportant in the Hamiltonian, in what concerns the dynamics.

This Hartree-Fock, or mean field approximation is slightly tricky to obtain. It requires one to be precise about what the meaning of the mean field approximation is in terms of creation and annihilation operators. In mean field theory, we assume that the operator

$$\rho_{\mu \mu'} = c_{\mu}^{\dagger} c_{\mu'} \quad (\text{A.2})$$

is close to its average, so that we neglect second order terms in the fluctuations  $\delta \rho_{\mu \mu'}$ , i.e.  $\rho_{\mu \mu'}$  is “large” only when its average is nonzero, otherwise it is negligibly small. Thus, for most combinations of indices, this operator will vanish. We follow the usual mean field procedure of writing the original operator as a deviation plus an average

$$c_{\nu}^{\dagger} \left( c_{\mu}^{\dagger} c_{\mu'} - \langle c_{\mu}^{\dagger} c_{\mu'} \rangle \right) c_{\nu'} + c_{\nu}^{\dagger} c_{\nu'} \langle c_{\nu}^{\dagger} c_{\nu'} \rangle \quad (\text{A.3})$$

Then we note that if  $\nu' \neq \mu$ , we can commute  $c_{\nu'}$  with the parenthesis. But this is true except in a set of measure zero. In the thermodynamic limit  $N \rightarrow \infty$ , the number of allowed  $\mathbf{k}$ -states is very large, and if we take a continuum limit in which the set of possible  $\mathbf{k}$ -states becomes dense, then the commutation becomes exact. Repeating the procedure of writing (A.3) replacing  $c_{\nu}^{\dagger} c_{\nu'} \mapsto c_{\nu}^{\dagger} c_{\nu'} - \langle c_{\nu}^{\dagger} c_{\nu'} \rangle + \langle c_{\nu}^{\dagger} c_{\nu'} \rangle$ , we obtain

$$\underbrace{(c_{\nu}^{\dagger} c_{\nu'} - \langle c_{\nu}^{\dagger} c_{\nu'} \rangle)(c_{\mu}^{\dagger} c_{\mu'} - \langle c_{\mu}^{\dagger} c_{\mu'} \rangle)}_{\propto \delta \rho_{\mu \mu'} \delta \rho_{\nu \nu'} \rightarrow 0} + c_{\nu}^{\dagger} c_{\nu'} \langle c_{\mu}^{\dagger} c_{\mu'} \rangle + c_{\mu}^{\dagger} c_{\mu'} \langle c_{\nu}^{\dagger} c_{\nu'} \rangle - \langle c_{\mu}^{\dagger} c_{\mu'} \rangle \langle c_{\nu}^{\dagger} c_{\nu'} \rangle \quad (\text{A.4})$$

But this result is not complete. This is only the so called Hartree or direct term. Due to identical nature of the interacting electrons, we must consider an analogous contribution for  $\langle c_{\nu}^{\dagger} c_{\mu'} \rangle$  finite. We start by exchanging the first two operators:

$$c_{\nu}^{\dagger} c_{\mu}^{\dagger} c_{\mu'} c_{\nu'} = -c_{\mu}^{\dagger} c_{\nu}^{\dagger} c_{\mu'} c_{\nu'} \quad (\text{A.5})$$

Then we proceed in exactly the same manner as before. The result is analogous, but a minus sign appears and we must switch  $\mu \leftrightarrow \nu$ :

$$- c_\mu^\dagger c_{\nu'} \langle c_\nu^\dagger c_{\mu'} \rangle - c_\nu^\dagger c_{\mu'} \langle c_\mu^\dagger c_{\nu'} \rangle + \langle c_\nu^\dagger c_{\mu'} \rangle \langle c_\mu^\dagger c_{\nu'} \rangle \quad (\text{A.6})$$

Ignoring the constant terms of the type  $\langle c^\dagger c \rangle \langle c^\dagger c \rangle$ , we recover equation (A.1).

Now we can simply substitute the mean field expansion of equation (A.1) in the second term to obtain the last term that is subtracted in equation (2.1) (we omit the boldface on the  $\mathbf{k}$ 's solely in the following equation, but keep in mind that they are vectors):

$$\begin{aligned} & \frac{1}{2} \sum_{\substack{k_1 k_2 k'_1 k'_2 \\ \sigma_1 \sigma_2}} V_{k'_1 k'_2}^{k_1 k_2} \left( - \underbrace{\langle c_{k_1 \sigma_1}^\dagger c_{k'_2 \sigma_2} \rangle}_{\delta_{k_1 k'_2} \delta_{\sigma_1 \sigma_2} f_{k_1}} c_{k_2 \sigma_2}^\dagger c_{k'_1 \sigma_1} - \underbrace{\langle c_{k_2 \sigma_2}^\dagger c_{k'_1 \sigma_1} \rangle}_{\delta_{k_2 k'_1} \delta_{\sigma_1 \sigma_2} f_{k_2}} c_{k_1 \sigma_1}^\dagger c_{k'_2 \sigma_2} + \underbrace{\langle c_{k_1 \sigma_1}^\dagger c_{k'_1 \sigma_1} \rangle}_{\delta_{k_1 k'_1} f_{k_1}} c_{k_2 \sigma_2}^\dagger c_{k'_2 \sigma_2} \right. \\ & \left. + \underbrace{\langle c_{k_2 \sigma_2}^\dagger c_{k'_2 \sigma_2} \rangle}_{\delta_{k_2 k'_2} f_{k_2}} c_{k_1 \sigma_1}^\dagger c_{k'_1 \sigma_1} \right) \end{aligned} \quad (\text{A.7})$$

In the language of Hartree Fock theory, the first two terms give the exchange term, and the last two terms the direct term. Apart from the  $\frac{1}{2}$  factor, the term in (A.7) becomes

$$\begin{aligned} & - \sum_{\substack{k_1 k_2 \\ k'_1 \sigma_1}} V_{k'_1 k_1}^{k_1 k_2} f_{k_1} c_{k_2 \sigma_1}^\dagger c_{k'_1 \sigma_1} - \sum_{\substack{k_1 k_2 \\ k'_2 \sigma_1}} V_{k_2 k'_2}^{k_1 k_2} f_{k_2} c_{k_1 \sigma_1}^\dagger c_{k'_2 \sigma_1} + \sum_{\substack{k_1 k_2 k'_2 \\ \sigma_1 \sigma_2}} V_{k_1 k'_2}^{k_1 k_2} f_{k_1} c_{k_2 \sigma_2}^\dagger c_{k'_2 \sigma_2} \\ & + \sum_{\substack{k_1 k_2 k'_1 \\ \sigma_1 \sigma_2}} V_{k'_1 k'_2}^{k_1 k_2} f_{k_2} c_{k_1 \sigma_1}^\dagger c_{k'_1 \sigma_1} \\ & = \sum_{k_1 k_2 \sigma_1} \left( 4V_{k_1 k_2}^{k_1 k_2} - 2V_{k_2 k_1}^{k_1 k_2} \right) f_{k_2} c_{k_1 \sigma_1}^\dagger c_{k_1 \sigma_1}, \end{aligned} \quad (\text{A.8})$$

where we used momentum conservation to eliminate a  $k'$ -sum. Moreover, we used that the sum on spin ( $\pm 1/2$ ) on the last two terms gives factors of 2, since the interaction is spin independent and thus no spin-dependent term remains after we use momentum conservation. Making  $k_1 \rightarrow k$ ,  $k_2 \rightarrow k'$ ,  $\sigma_1 \rightarrow \sigma$ , and recalling the definition in equation (2.2), we obtain the result we sought.

The procedure above is meant to serve as an intuitive derivation. Now we approach the problem more formally. In fact, the argument that allowed us to perform the commutation leading to equation A.4 seems somewhat handwaving. We should not have to take the thermodynamic limit to perform a mean field expansion. A more systematic procedure to obtain the mean field expansion of a quartic interaction term was given by Pierre de Gennes in the context of a mean field treatment of a superconductor in a magnetic field [deGennes1999]. Our case is actually much simpler to analyze, but we follow the same argument as de Gennes.

Consider the Hamiltonian to be given by  $\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_1$ , where

$$\begin{aligned}\mathcal{H}_0 &= \sum_{\mathbf{k}, \sigma} \varepsilon_{\mathbf{k}} c_{\mathbf{k}, \sigma}^\dagger c_{\mathbf{k}, \sigma} \\ \mathcal{H}_1 &= \frac{1}{2} \sum_{\substack{\mathbf{k}_1 \mathbf{k}_2 \\ \mathbf{k}'_1 \mathbf{k}'_2 \\ \sigma_1 \sigma_2}} V_{\mathbf{k}'_1 \mathbf{k}'_2}^{k_1 k_2} c_{\mathbf{k}_1 \sigma_1}^\dagger c_{\mathbf{k}_2 \sigma_2}^\dagger c_{\mathbf{k}'_2 \sigma_2} c_{\mathbf{k}'_1 \sigma_1}\end{aligned}\tag{A.9}$$

We would like to find an effective Hamiltonian that is quadratic in the fermion operators:

$$\mathcal{H}_{\text{eff}} = \sum_{\mathbf{k}, \sigma} (\varepsilon_{\mathbf{k}} + v_{\mathbf{k}}) c_{\mathbf{k}, \sigma}^\dagger c_{\mathbf{k}, \sigma}\tag{A.10}$$

This effective Hamiltonian is diagonal, so assuming we know  $v_{\mathbf{k}}$  (which is what we are trying to determine in the first place), we can compute its eigenstates  $\{|\phi\rangle\}$ , and compute the average of the actual Hamiltonian  $\mathcal{H}$  using the basis  $\{|\phi\rangle\}$ :

$$\langle \mathcal{H} \rangle = \frac{\sum_{\phi} \langle \phi | \mathcal{H} | \phi \rangle e^{-\beta E_{\phi}}}{\sum_{\phi} e^{-\beta E_{\phi}}}\tag{A.11}$$

Our criterion to determine  $\mathcal{H}_{\text{eff}}$  is the requirement that the free energy  $F = \langle \mathcal{H} \rangle - TS$ , with the average computed with the eigenstates of  $\mathcal{H}_{\text{eff}}$  be stationary, i.e.  $\delta F = 0$ . Thus, we find the mean field form of the quartic term invoking only a variational principle without any need to resort to the thermodynamic limit. In fact, we never even have to explicitly compute the average in equation (A.11). In terms of pairs of fermion operator averages, we have

$$\langle \mathcal{H} \rangle = \sum_{\mathbf{k}, \sigma} \varepsilon_{\mathbf{k}} \left\langle c_{\mathbf{k}, \sigma}^\dagger c_{\mathbf{k}, \sigma} \right\rangle + \frac{1}{2} \sum_{\substack{\mathbf{k}_1 \mathbf{k}_2 \\ \mathbf{k}'_1 \mathbf{k}'_2 \\ \sigma_1 \sigma_2}} V_{\mathbf{k}'_1 \mathbf{k}'_2}^{k_1 k_2} \left\langle c_{\mathbf{k}_1 \sigma_1}^\dagger c_{\mathbf{k}_2 \sigma_2}^\dagger c_{\mathbf{k}'_2 \sigma_2} c_{\mathbf{k}'_1 \sigma_1} \right\rangle,\tag{A.12}$$

where the last term can be reduced to products of averages of pairs of fermion operators by Wick's theorem:

$$\begin{aligned}\left\langle c_{\mathbf{k}_1 \sigma_1}^\dagger c_{\mathbf{k}_2 \sigma_2}^\dagger c_{\mathbf{k}'_2 \sigma_2} c_{\mathbf{k}'_1 \sigma_1} \right\rangle &= \left\langle c_{\mathbf{k}_1 \sigma_1}^\dagger c_{\mathbf{k}'_1 \sigma_1} \right\rangle \left\langle c_{\mathbf{k}_2 \sigma_2}^\dagger c_{\mathbf{k}'_2 \sigma_2} \right\rangle - \left\langle c_{\mathbf{k}_1 \sigma_1}^\dagger c_{\mathbf{k}'_2 \sigma_2} \right\rangle \left\langle c_{\mathbf{k}_2 \sigma_2}^\dagger c_{\mathbf{k}'_1 \sigma_1} \right\rangle \\ &+ \left\langle c_{\mathbf{k}_1 \sigma_1}^\dagger c_{\mathbf{k}_2 \sigma_2}^\dagger \right\rangle \left\langle c_{\mathbf{k}'_2 \sigma_2} c_{\mathbf{k}'_1 \sigma_1} \right\rangle\end{aligned}\tag{A.13}$$

The computation is now done by using the rules (for all  $\mathbf{k}$  and  $\sigma$ ).

$$\begin{aligned}\left\langle c_{\mathbf{k}, \sigma}^\dagger c_{\mathbf{k}', \sigma'} \right\rangle &= \delta_{\mathbf{k}, \mathbf{k}'} \delta_{\sigma, \sigma'} f_{\mathbf{k}} \\ \left\langle c_{\mathbf{k}, \sigma}^{(\dagger)} c_{\mathbf{k}', \sigma'}^{(\dagger)} \right\rangle &= 0,\end{aligned}\tag{A.14}$$

where  $f_{\mathbf{k}} = (e^{\beta(\varepsilon_{\mathbf{k}} - \mu)} + 1)^{-1}$  is the Fermi-Dirac function.

Since the original Hamiltonian is quadratic, again we have that terms of the type  $\langle cc \rangle$  and  $\langle c^\dagger c^\dagger \rangle$  do not contribute. Hence, varying the free energy, we obtain

$$\delta F = \delta \langle \mathcal{H} \rangle - T\delta S = \sum_{\mathbf{k}\sigma} \varepsilon_{\mathbf{k}} \delta \left\langle c_{\mathbf{k},\sigma}^\dagger c_{\mathbf{k},\sigma} \right\rangle + \frac{1}{2} \sum_{\substack{\mathbf{k}_1 \mathbf{k}_2 \\ \mathbf{k}'_1 \mathbf{k}'_2 \\ \sigma_1 \sigma_2}} V_{\mathbf{k}'_1 \mathbf{k}'_2}^{k_1 k_2} \left( \left\langle c_{\mathbf{k}_1 \sigma_1}^\dagger c_{\mathbf{k}'_1 \sigma_1} \right\rangle \delta \left\langle c_{\mathbf{k}_2 \sigma_2}^\dagger c_{\mathbf{k}'_2 \sigma_2} \right\rangle + \right. \\ \left. \delta \left\langle c_{\mathbf{k}_1 \sigma_1}^\dagger c_{\mathbf{k}'_1 \sigma_1} \right\rangle \left\langle c_{\mathbf{k}_2 \sigma_2}^\dagger c_{\mathbf{k}'_2 \sigma_2} \right\rangle - \left\langle c_{\mathbf{k}_1 \sigma_1}^\dagger c_{\mathbf{k}'_2 \sigma_2} \right\rangle \delta \left\langle c_{\mathbf{k}_2 \sigma_2}^\dagger c_{\mathbf{k}'_1 \sigma_1} \right\rangle - \delta \left\langle c_{\mathbf{k}_1 \sigma_1}^\dagger c_{\mathbf{k}'_2 \sigma_2} \right\rangle \left\langle c_{\mathbf{k}_2 \sigma_2}^\dagger c_{\mathbf{k}'_1 \sigma_1} \right\rangle \right) - T\delta S, \quad (\text{A.15})$$

which can be simplified exactly in the same manner as in equation (A.7), i.e. by using the rules of equation (A.14), and that the occupation of a given momentum state  $\mathbf{k}$  is given by the Fermi-Dirac function:

$$\delta F = \sum_{\mathbf{k}\sigma} \varepsilon_{\mathbf{k}} \delta \left\langle c_{\mathbf{k},\sigma}^\dagger c_{\mathbf{k},\sigma} \right\rangle + \sum_{\mathbf{k}\mathbf{k}'\sigma} \left( 2V_{\mathbf{k}\mathbf{k}'}^{\mathbf{k}\mathbf{k}'} - V_{\mathbf{k}'\mathbf{k}'}^{\mathbf{k}\mathbf{k}'} \right) f_{\mathbf{k}'} c_{\mathbf{k}\sigma} \delta \left\langle c_{\mathbf{k},\sigma}^\dagger c_{\mathbf{k},\sigma} \right\rangle \quad (\text{A.16})$$

We can now compare  $\delta F = \delta \langle \mathcal{H} \rangle - T\delta S$  and  $\delta F' = \delta \langle \mathcal{H}_{\text{eff}} \rangle - T\delta S$ , which is simply given by

$$\delta F' = \delta \langle \mathcal{H}_{\text{eff}} \rangle - T\delta S = \sum_{\mathbf{k}\sigma} (\varepsilon_{\mathbf{k}} + v_{\mathbf{k}}) \delta \left\langle c_{\mathbf{k},\sigma}^\dagger c_{\mathbf{k},\sigma} \right\rangle \quad (\text{A.17})$$

Requiring both free energies to be stationary, we find our desired result

$$v_{\mathbf{k}} = \sum_{\mathbf{k}'} \left( 2V_{\mathbf{k}\mathbf{k}'}^{\mathbf{k}\mathbf{k}'} - V_{\mathbf{k}'\mathbf{k}'}^{\mathbf{k}\mathbf{k}'} \right) f_{\mathbf{k}'}, \quad (\text{A.18})$$

which agrees with the result obtained from our initial more intuitive, but somewhat less rigorous argument.

# B

Computing the partition function for a  
quadratic Hamiltonian

Let us start by restating the result we want to prove.

If  $\mathcal{H} = \mathbf{c}^\dagger \mathbf{H} \mathbf{c}$ , where  $\mathbf{H}$  is a  $N \times N$  Hermitian matrix, then we have that

$$\text{Tr}[e^{-\beta \mathcal{H}}] = \prod_{i=1}^N (1 + e^{-\beta \lambda_{k_i}}), \quad (\text{B.1})$$

where  $\lambda_{k_i}$  are the eigenvalues of  $\mathbf{H}$ .

We will now prove equation (B.1). Without loss of generality, let us consider  $\mathbf{H}$  to be diagonal. Then, its eigenvalues coincide with the diagonal entries, so that  $\mathbf{H} = \text{diag}(\lambda_{k_i})$ . The quadratic Hamiltonian may then be diagonalized

$$\mathcal{H} = \mathbf{c}^\dagger \text{diag}(\lambda_{k_1}, \lambda_{k_2}, \dots, \lambda_{k_N}) \mathbf{c} = \sum_{i=1}^N \lambda_{k_i} n_{k_i}$$

We continue by induction. When  $N = 1$ , we have

$$\text{Tr}(e^{-\beta \mathcal{H}}) = \langle 0 | e^{-\beta \lambda_{k_1} n_{k_1}} | 0 \rangle + \langle 1 | e^{-\beta \lambda_{k_1} n_{k_1}} | 1 \rangle = 1 + e^{-\beta \lambda_{k_1}} \quad (\text{B.2})$$

Assuming that for  $N - 1$ :

$$\text{Tr}[e^{-\beta \sum_{i=1}^{N-1} \lambda_{k_i} n_{k_i}}] = \prod_{i=1}^{N-1} (1 + e^{-\beta \lambda_{k_i}})$$

we can compute the trace for  $i$  going up to  $N$ .

$$\begin{aligned} \text{Tr}[e^{-\beta \sum_{i=1}^{N-1} \lambda_{k_i} n_{k_i}}] &= \sum_{\{k_i\}_{i=1}^N} \left\langle \psi_1^{k_1} \psi_2^{k_2} \dots \psi_N^{k_N} \middle| e^{-\beta \sum_{i=1}^N \lambda_{k_i} n_{k_i}} \middle| \psi_1^{k_1} \psi_2^{k_2} \dots \psi_N^{k_N} \right\rangle \\ &= \sum_{\{k_i\}_{i=1}^{N-1}} \left( \left\langle \{\psi_i^{k_i}\} 0 \middle| e^{-\beta \sum_{i=1}^N \lambda_{k_i} n_{k_i}} e^{-\beta \lambda_{k_N} n_{k_N}} \middle| \{\psi_i^{k_i}\} 0 \right\rangle + \left\langle \{\psi_i^{k_i}\} 1 \middle| e^{-\beta \sum_{i=1}^N \lambda_{k_i} n_{k_i}} e^{-\beta \lambda_{k_N} n_{k_N}} \middle| \{\psi_i^{k_i}\} 1 \right\rangle \right) \\ &= (1 + e^{-\beta \lambda_{k_N}}) \sum_{\{k_i\}_{i=1}^{N-1}} \left\langle \{\psi_i^{k_i}\} \middle| e^{-\beta \lambda_{k_i} n_{k_i}} \middle| \{\psi_i^{k_i}\} \right\rangle \\ &= (1 + e^{-\beta \lambda_{k_N}}) \prod_{i=1}^{N-1} (1 + e^{-\beta \lambda_{k_i}}) \\ &= \prod_{i=1}^N (1 + e^{-\beta \lambda_{k_i}}) \end{aligned}$$

To complete the proof we note that for any  $\mathbf{H}$ , there exists a unitary matrix  $\mathbf{Q}$ , such that  $\mathbf{Q}^T \mathbf{H} \mathbf{Q} = \mathbf{\Lambda} = \text{diag}(\lambda_{k_i})$ . Let  $\tilde{\mathbf{c}} = \mathbf{Q} \mathbf{c}$ , and  $\tilde{n}_i = \tilde{c}_i^\dagger \tilde{c}_i$ . Then, we find

$$\mathcal{H} = \mathbf{c}^\dagger \mathbf{H} \mathbf{c} = \tilde{\mathbf{c}}^\dagger \mathbf{\Lambda} \tilde{\mathbf{c}} = \sum_{i=1}^N \lambda_{k_i} \tilde{n}_{k_i}$$

The trace is independent of the choice of basis functions. Thus, we have

$$\begin{aligned}
\text{Tr}(e^{-\beta \mathcal{H}}) &= \text{Tr} \left( \prod_{i=1}^N e^{-\beta \lambda_{k_i} \tilde{n}_{k_i}} \right) \\
&= \prod_{i=1}^N \left( 1 + e^{-\beta \lambda_{k_i}} \right) \quad \square
\end{aligned}$$
